Preoperative care is directed toward (1) *reduction of edema* and (2) *elimination of infection*. Generally the wearing of an Ace type of bandage with periods of elevation during the day and at night will suffice to reduce edema. For the most severe cases 1 to 2 weeks in bed at home may be necessary. It is hard to get co-operation from some individuals so that it may be necessary to admit them to the hospital 4 to 7 days preoperatively for close supervision. Hot saline soaks for infected ulcerations are carried out daily with appropriate dressings. These can be augmented by potassium permanganate 1:5000 soaks should fungous infection be present. In stout people weight reduction is begun immediately. The obese often have a troublesome groin intertrigo which must be cleared up before operation can be safely done. Frequent baths are followed by thorough drying sprinkling with thymol iodide powder and the insertion of gauze between the skin folds to keep the area dry. In cases of acute saphenous thrombophlebitis in which early ligation is to be done, it is my custom to give sulfadiazine several days before and after operation. This step is rarely necessary following femoral thrombophlebitis because the time lapse between acute infection and operation is sufficiently long (6 to 12 months) for infection to subside. If sclerosis is to be done, a preliminary test injection of 0.3 cubic centimeter of sodium ricinoleate is made into a suitable varix.

The patient is admitted to the hospital the evening before operation. For high saphenous and 'blowout' ligations the skin is shaved from toes to umbilicus and a low enema is given. Nembutal 1½ or 3 grains is given for sleep and repeated the following morning 1½ hours before operation. Morphine sulfate 1/6 grain and scopolamine 1/150 grain are given 45 minutes before operation. Most patients will then sleep soundly during the operative procedure. Immediately before the patient lies on the table the location of 'blowouts' is checked and the actual lines of incision marked heavily with indelible pencil.

Choice of operation Patients showing incompetence of the saphenofemoral valve should have

a *high saphenous ligation* with division of all tributaries. Incompetent perforators should be excised. *Retrograde sclerosis* after the method of Pratt is done in uncomplicated cases. Sclerosis is contraindicated (1) following acute saphenous thrombophlebitis (2) in the presence of vaso-spastic disease of the lower extremities—painful moist postphlebotic extremities with or without ulceration react unfavorably and sometimes alarmingly to sclerosis—(3) in the presence of obliterative or other peripheral vascular disease as for example, arteriosclerosis or thromboangitis obliterans, (4) following abnormal reactions to the test dose such as urticaria, asthma, severe local pain or inflammatory reaction.

If the saphenofemoral valve is intact it is only necessary to excise any 'blowouts' which may be present or to ligate the lesser saphenous vein at its termination. I also excise many extremely dilated segments as these are obliterated with difficulty and may break down following retrograde sclerosis. If the saphenous vein is dilated through out, I usually interrupt it just below or just above the knee even in the absence of 'blowouts'. This lessens the tendency to recanalization of thrombosed varices in the calf and leg.

Operative technique Shoulder pieces are installed so that moderate Trendelenburg position can be used if desired. Many large varices remain distended when the patient is in the flat position. This distention is undesirable if retrograde sclerosis is contemplated. The excess blood dilutes and 'puddles' the sclerotic and causes excessive clot formation. About 10 or 15 degrees of Trendelenburg position is sufficient to drain the venous channels and is done when necessary. This appears to be more easily done than the bandaging technique of Pearce. It also leaves the legs free for secondary ligation.

The operative technique is modified from that of Pratt. Local anesthesia with 1 per cent procaine hydrochloride is used. A point 1 inch (2.5 cm.) below and 1 inch (2.5 cm.) lateral to the spine of the pubis is selected and an intradermal bleb is made (Fig. 6). This spot should be over the saphenous bulb and occupies the center of the incision. In obese people the inguinal fold may be considerably below this spot. It may even be necessary as Dunlop suggests to make the wound on top of the fatty apron. The line of incision, parallel to Poupert's ligament is infiltrated and the area anesthetized through the original bleb by advancing and retracting the needle point fanwise through the subcutaneous tissue. If the point of the needle is in continuous motion it is not necessary to test for vascular penetration by

Fig. 6. Location of incision.

withdrawing the syringe. About 40 cubic centimeters of the anesthetic are generally used.

An incision 2 to 3 inches (5.0 to 7.5 cm.) long is made, depending on the thickness of the fatty layer. The operation is more quickly and safely done through an adequate incision. The vein is

safely exposed by sharp dissection as traction is applied to the wound edges. Two layers of substantial superficial fascia are met and divided. In thin persons the deeper layer lies close to the vein. In the obese there is often considerable fat under this fascia through which the vein runs. Retraction is by means of spring self-retaining retractors. The vein is usually met at about the level of its lowermost tributary. It is dissected free from its bed. Exposure of the saphenous bulb is then completed by separating adventitia and fascia from the vein and dividing upward. This makes necessary a minimum of retraction (Fig. 7). In the majority of cases the superficial external pudendal artery crosses over the bulb. It serves as a landmark and may be divided if necessary. Often the artery passes next beneath the saphenous vein and occasionally it divides, sending small branches both over and under the vein.

The saphenous is freed up to its confluence with the femoral and all tributaries are divided between ligatures of No. 0 chromic catgut. From three to five are usually encountered. The saphenous is then ligated as high as possible with chromic No. 0 catgut. It is clamped distal to the and again 1 inch (2.5 cm.) lower. The intervening vein is removed. The proximal stump is secured with a C silk transfusion ligature distal to the first tie.

The distal stump is grasped laterally with clamps (Fig. 8) and the occluding clamp is re-

Fig. 7. Fascia lifted upward along course of vein to facilitate exposure of saphenous bulb and ligation of tributaries.

moved. A ligature of chromic No 0 catgut is readied with a half knot and a No 6 French ureteral catheter is introduced into the vein. It will usually enter 25 to 50 centimeters without difficulty. Occasionally the tip catches in a valve leaflet or tributary opening. Partial withdrawal and axial rotation of the catheter will usually enable it to slide past these obstacles but one must be careful not to push too hard as the vein wall is easily penetrated.

This procedure must be done quickly as the vein goes into spasm almost immediately. If the catheter becomes blocked and must be withdrawn reinsertion is almost impossible. When the catheter is at maximum insertion the half knot is tightened to prevent regurgitation and wet saline sponges are packed about the vein opening to prevent any back flow into the tissues. From 30 to 100 cubic centimeters of 3½ per cent sodium picnolate solution are injected depending on the size of the varices and the depth of insertion of the catheter. Twenty five per cent of the sclerosing is first injected and the remainder is distributed uniformly along the course of the vein as the catheter is withdrawn. Occasionally one is unable to penetrate further than 20 centimeters or so even in the presence of a large saphenous vein. This is usually due to excessive tortuosity. The sclerosing solution can then be distributed distally by means of a gentle sweeping massage while it is being injected. A larger amount can be introduced with safety and more complete sclerosis obtained. The knot is completed and reinforced with a C silk transfixion applied above the catheter. (If the vein is penetrated below this the

Fig 9. Operative site ready for closure. Thoroughly irrigated with saline.

sclerosing solution will leak.) The wound is irrigated with saline (Fig 9). Several interrupted line catgut sutures are placed in the superficial fascia and the skin is united with interrupted silk vertical mattress sutures.

While the assistant closes the wound the surgeon attends to the blowouts. The previously marked lines of incision 1 to 2 inches long are heavily infiltrated with 1 per cent procaine. This infiltration serves to separate superficial veins from the skin to which they closely adhere following phlebitis or chronic dermatitis and edema of long standing. The skin is cleanly incised and retracted with small rakes. Allis clamps necrotize the skin and should never be used to grasp skin edges. The vein is grasped, freed and all available tributaries are clamped and divided. The T shaped junction between vessel and perforator is sought. The vein is divided above and below between clamps to prevent escape of the sclerosing solution. Should any escape the wound must be immediately flushed with saline. The vessels are tied with No 00 plain catgut. Chromic catgut was found to be poorly absorbed by this thickened poorly vascularized tissue particularly in the lower leg. The wound is closed loosely with two or three vertical mattress silk sutures.

Ligation of the lesser saphenous is accomplished in a similar fashion (Fig 10).

Dressing must be carefully done. The femoral incision is entirely sealed with adhesive especially in women. The lower gauze dressings are held in place with diagonal rather than circumferential

Fig 8. Technique of retrograde sclerosis. Half knot; retracts reflux.

Fig. 1. Varicosities of lesser saphenous system. a, Posterior view. Large venous channel marked where it lies beneath fascia. X marks site of ligation. b, Oblique view. Note enlarged greater saphenous coursing down medial aspect of knee. An excellent result was obtained in this case by ligating and sclerosing both greater and lesser saphenous veins.

strips of adhesive to obviate tension in the event of swelling. If retrograde sclerosis has been done the femoral and leg regions, groin to ankle, are padded with combination dressings and the entire extremity bandaged firmly with two 4 inch Ace type bandages. If sclerosis has not been done, it is unnecessary to pad the leg but a 4 inch Ace type bandage is applied from toes to knee.

Postoperative care. Immediately the operative dressing is finished the patient is made to walk for 5 to 10 minutes. This distributes the sclerosing solution more evenly enhancing its effect. 'Puddling' is prevented and danger from vein break down and its attendant difficulties is minimized. Following this, the patient goes to bed. Thereafter he is required to walk 10 to 15 minutes every 2 hours until he becomes completely ambulatory. The outer bandages are removed after 6 hours and additional padding is placed over any point which seems unduly irritated. The padding is discarded

after 3 to 5 days. The Ace bandages are replaced daily. Most patients go home wearing Ace bandages to the knee only. If the varices above the knee are large, it may be necessary to bind the thigh for 2 to 3 weeks. When retrograde sclerosis is done the average hospital stay is 4 days if one, and 6 days if both sides are operated upon. If simple ligation has been done, the patient usually goes home the following day.

The Ace bandages (or well fitting stockings) are worn for from 8 to 12 weeks or until sclerosis is complete, being removed only to bathe or when the patient is in bed. When sclerosis is complete the Ace bandages are discarded *gradually*. The legs will swell if this is not done as vascular tone takes time to return. I have the patient put on the Ace bandages as usual in the morning and wear them until late afternoon, when they are removed. If no swelling appears by bed time, the bandages are removed the next day in midafternoon. Thus the hour of removal gradually becomes earlier until the patient goes without bandages entirely.

Postoperative injections. Where simple ligation has been done injections are begun as soon as the wounds are well healed, i.e. 10 to 14 days. Multiple (three or four) punctures at one visit can be made as tolerated. I do not inject more than 1.5 cubic centimeters in one place or more than 50 cubic centimeters at any one time.

If retrograde sclerosis has been done one should wait at least a month before injecting any remaining veins. Frequently no further injections are necessary. It is my experience that many vein segments not initially thrombosed will become so without injection during the first 4 weeks after operation. The average patient, however needs 3 to 6 injections to complete the obliteration of the varices. I prefer to give an extra injection or two later than inject too much sclerosing agent at the time of operation. Pratt originally used 20 to 40 cubic centimeters of solution. I use about one quarter of this quantity.

Complications

1 Postoperative reactions. A febrile response to retrograde sclerosis occurs depending on (a) the amount injected, (b) the size of the varices, and (c) whether both legs are done. On the second and third days the temperature may reach 100.5 to 101.0 degrees F. Occasionally it is higher. This need occasion no alarm because better and more complete sclerosis occurs after increased febrile response. However reaction higher than 103 degrees F is considered abnormal. Although I have noted no permanent ill effects, these patients

should be watched closely. I have seen several instances in which the temperature reached 105 degrees F on the third postoperative day and one instance in which it reached 107.4 degrees F. All these complications were either in postphlebitic patients or in patients who showed signs of heightened vascular irritability. These patients were kept in bed with the legs elevated. Papaverine $\frac{1}{2}$ to 2 grains was given every 4 hours to lessen vascular spasm. Paravertebral novocain fluid was used in the more severe cases and extra fluids were administered. Possibly these reactions could have been avoided with proper selection of cases for sclerosis.

2 *Femoral thrombosis*. I have observed no case of femoral thrombosis—a fact attributable to the exclusive use of local anesthesia which makes the patient immediately ambulatory.

3 *Hemorrhage*. No serious bleeding has been encountered following the use of silk transfexion of the saphenous stump. Occasionally the femoral bandage becomes blood soaked during the period immediately after operation. This seepage of blood can always be controlled by pressure.

4 *Infection*. Avoidance of infection depends, I believe on (a) the use of a single puncture wound for anesthesia, (b) delay of operation until dermatitis and other infections are cleared up, (c) avoidance of injury to enlarged femoral lymph nodes during operation, (d) prevention of contamination by proper dressing and the covering of the wound surface with sulfanilamide powder.

5 *Delayed healing of wounds*. Delayed healing of wounds frequently occurs without infection and only in the lower leg wounds. The lower the incision the more liable is healing to be slow. Healing is frequently delayed about the ankle when incision has been made through edematous, chronically inflamed skin. This difficulty is met with elevation, warm soaks, and suitable dressings.

Follow-up

The patients are seen at intervals after sclerosis is completed. The legs are inspected at the time the Ace bandages are discarded and again 3 months later. After this I see them at intervals of 6 months. Any visible additional varices can then be injected. New varices occur and are not to be mistaken for recurrences. Occasionally recanalization of certain channels occurs. This has been due usually to the presence of a blowout missed at the initial examination. Simple excision of the blowout followed by an injection or two remedies the situation.

SUMMARY

The origin of varicose veins is discussed and their anatomical types are enumerated together with the several types of bodily configuration in which varicose veins are most liable to occur. Different methods of treatment and their indications are outlined. Injection of veins and operative technique are discussed in detail. Contra-indications to the use of sclerosing solutions include (1) saphenous thrombophlebitis, (2) vasospastic disease of the lower extremities, (3) obliterative peripheral vascular disease, (4) abnormal reactivity to the test dose. Postoperative complications, their avoidance and treatment are described. Analysis of cases and late results will be the subject of further communication when more time has elapsed.

ADENOCARCINOMA CYLINDROMA TYPE OF THE PAROTID GLAND

A Clinical and Pathologic Study of Twenty One Cases

FRANK W QUATTLEBAUM M D MALCOLM B DOCKERTY M D AND CHARLES W MAYO M D FACS Rochester Minnesota

IN a previous study by two of us (Dockerty and Mayo 4) it was pointed out that there occasionally arose in the submaxillary salivary gland a type of neoplasm variously known as cylindroma¹ adenocarcinoma cylindroma type or basal cell carcinoma with hyaline stroma. The incidence of this tumor in a large series of submaxillary glandular neoplasms, was approximately 20 per cent. Throughout the literature as well as in our own series this tumor had been confused with the ordinary type of mixed salivary glandular neoplasms. In this group of cylindromas recurrence was extremely high and metastasis frequent with more than 50 per cent of patients succumbing from the effects of widespread dissemination of the disease. Clinically cylindromas could not be distinguished from the group of mixed tumors although pain was a contrastingly frequent symptom. Surgically the infiltrative tendencies observed by the surgeon made him sometimes question a fresh tissue diagnosis of cellular mixed tumor. However in this previous communication distinctive microscopic features of cylindroma were presented and it was shown that the surgical pathologist familiar with the cellular pattern could render a real service in advising radical operative procedures when such a neoplasm was encountered.

More recent experiences (5) demonstrated that adenocarcinomas of the cylindroma type affecting the tongue and the parotid gland were also dangerous from the standpoint of metastasis. Mulligan, in a recent review reported instances of 12 metastasizing mixed tumors, many of which had been primary in the parotid gland. Interestingly enough most of the illustrations in his article duplicated the microscopic appearance of

Workment of these submitted by Dr. Quattlebaum to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of M. S. in Surgery.

After this paper was written Dr. Quattlebaum and Dr. Mayo entered the armed services and became Lieutenant and Colonel, respectively Medical Corps, Army of the United States.

The term "cylindroma" never used in this paper appears as an abbreviation for "adenocarcinoma of the type cylindroma."

cylindroma in all major features. Since investigators still confuse mixed tumors with cylindromas and Bauer and Fox, on the basis of 3 tumors, stated that cylindromas are generally benign, it was thought advisable to consider a group of primary neoplasms of the parotid to ascertain whether or not cylindromas occurred there and, if so, whether or not their clinical behavior was that of their submaxillary counterpart.

MATERIALS AND METHODS

Material was available on 210 consecutive cases in which primary parotid neoplasms had been removed surgically at the Mayo Clinic between the years 1928 and 1936 inclusive. This particular group of specimens was selected because it represented a series large enough to warrant conclusions as to the probable general incidence of parotid cylindromas and because it allowed ample time for a follow up in the cases occurring in the later years of the series.

Before any records were reviewed these 210 formalin-preserved tumors were carefully studied in gross detail special attention being paid to the features of size, color, consistency, presence or absence of encapsulation, amount of parotid glandular tissue removed, presence of attached lymph nodes and so forth. Multiple blocks were cut from the tumors, the adjacent salivary gland, and regional lymph nodes when available. These blocks were placed in a 10 per cent solution of fresh formalin sectioned at a thickness of approximately 10 microns and stained routinely with hematoxylin and eosin. Study of these sections brought to light 21 tumors which, although in many instances previously labeled atypical mixed tumors, seemed to fulfill the criteria for a revised diagnosis of adenocarcinoma of the cylindroma type. The present report deals with the clinical and pathologic details of this group of 21 cases.

PATHOLOGIC DATA

Gross features. In 19 cases the material was such as to suggest that total or subtotal removal of the tumor had been performed and in 2 instances

Fig. 1 Grade 2 adenocarcinoma, cylindroma type illustrating resemblance to basal cell carcinoma. The honeycombed plaques of malignant cells are distinctive, as is also the hyaline stroma. The so-called capsule shown in the upper portion of the photomicrograph is extensively invaded by malignant cells (hematoxylin and eosin $\times 44$).

Fig. 2 Grade 2 adenocarcinoma, cylindroma type illustrating again the basic architecture in addition to the phenomenon of perineural invasion by carcinoma cells (hematoxylin and eosin $\times 44$).

only a small biopsy specimen was available for study. All of the tumors were unilateral. In 4 cases the entire parotid gland was attached to large neoplasms of an infiltrative type and in 2 additional instances the presence of attached malignant appearing cervical nodes indicated that fairly extensive operations had been performed. In 7 of the remaining 17 cases the tumor appeared in the form of single or multiple grayish white encapsulated nodules. Rarely could the capsule be separated with ease from the underlying tumor tissue. Nonencapsulated examples always demonstrated invasion of attached parotid glandular tissue or the surrounding adipose connective tissue and portions of striated muscle which were occasionally removed with the operative specimen. In 1 case an attached portion of the mandibular ramus was grossly invaded by neoplastic tissue.

Microscopic features. The microscopic appearance of these tumors differed in no essential respect from that detailed in a previous study (Figs. 1 to 6). The general architecture was that of islands and strands of small dark-staining cells with hyperchromatic nuclei. Many of the units demonstrated central honeycombing with clear

spaces which in some instances were filled with hyaline substance, in others were occupied by globules of material which stained positively for mucus and in still others were empty. The stroma was in general hyaline. Infiltrative tendencies were pronounced the tumor capsule, the attached parotid glandular substances, the surrounding fat and so forth frequently demonstrating invading strands of tumor tissue running out from the parent growth. Perineural involvement was observed in all 11 instances in which nerve fibers were found. Metaplasia to epithelium of a squamous type was noted in 2 tumors. All the other neoplasms were pure adenocarcinomas of the type cylindroma, 14 being of grade 2 and 7 of grade 1 malignancy according to the method of Broders. In 2 instances portions of the neoplasm demonstrated appearances somewhat typical of mixed tumor. Previous experience had taught us that this group of 'intermediates' ran the clinical course of cylindromas and accordingly they were included in the present series.

CLINICAL DATA

Incidence. The incidence of parotid adenocarcinomas of the cylindroma type was 10 per cent of the entire group. Stein and Geschickter observed

Fig. 3. Grade 3 adenocarcinoma, cylindroma type, illustrating marked cellularity, poor glandular formation and infiltration with splitting of the capsule. Excision in this case would have left behind multiple tumor seedlings (hematoxylin and eosin $\times 10$).

Fig. 4. Grade 1 adenocarcinoma, cylindroma type, is a picture of good acinar formation and other evidence of cellular differentiation. The infiltrative propensity is evidenced with the invasion of fat (hematoxylin and eosin $\times 44$).

a 15 per cent incidence of this type. The corresponding figure for the submaxillary salivary gland was 18.5 per cent according to Dockerty and Mayo (4).

Sex. Men and women were almost equally represented in this series, in keeping with the observation in the literature that salivary glandular neoplasms have no particular sex predilection.

Age. The average age of the patients was 49.8 years with extremes of 32 years and 65 years.

Symptoms. The commonest symptom related by the patients was the presence of a tumor with an incidence of 100 per cent. The duration of the swelling varied from 6 months to 15 years with an average of about 7 years. It was thus impossible to judge, on the basis of this symptom alone, the nature of the underlying pathologic process.

Half of the patients additionally complained of pain which was constant and localized in 2 instances and intermittent and lancinating in the remainder. Six patients had experienced extension of pain across the face, over the forehead or down into the neck, the character and distribution indicating irritation or actual invasion of a nerve by the tumor. In our experience pain was an unusual feature in connection with mixed salivary

glandular neoplasms and its presence in patients suffering from primary parotid and submaxillary swellings should make one alert to a possible underlying adenocarcinoma of the cylindroma type.

On physical examination 10 tumors involved the right and 11 the left parotid gland. All tumors were unilateral. Location was generally described as being preauricular with certain tumors varying in occupying a high or a low position. The average estimated size was 4.5 centimeters with variations from 1 to 7 centimeters. Whereas 10 of the tumors were somewhat movable, resembling mixed tumor in this regard, the remainder were described as being fixed a feature suggesting the presence of infiltration. As pointed out previously, local fixation of the tumor is an important sign in distinguishing adenocarcinoma of the cylindroma type from mixed tumors of the salivary glands. Partial or complete paralysis of the facial nerve was present in 25 per cent of the cases at the time of first examination at the clinic. Whereas in several instances it is possible that this paralysis follows the performance of a previous operation we feel on the basis of pathologic studies that it is most often brought about through perineural invasion of the seventh nerve.

Fig 5. Grade 2 adenocarcinoma, cylindroma type. This neoplasm was "recurrent" and illustrates extensive invasion of striated muscle (hematoxylin and eosin $\times 44$).

Fig 6. Grade 2 adenocarcinoma, of the cylindroma type, with the invasion of a lymph node (hematoxylin and eosin $\times 44$).

At operation only 39 per cent of the tumors were invested by anything which could be described as being a capsule, the remainder demonstrating evidence of infiltration. It was estimated that complete excision was accomplished in 50 per cent of the cases. However, several of the cases in which the surgeon made a note regarding residual tumor tissue were instances in which previous operation had been performed and the neoplasm was listed as a recurrence.

TREATMENT AND RESULTS

Treatment consisting of wide local excision alone or combined with postoperative therapy using roentgen rays was employed in 15 cases. Complete parotidectomy was performed 4 times for large neoplasms, 1 of which represented a recurrence following a previous "local" operative procedure. In the 2 remaining instances biopsy followed by roentgen therapy was the therapeutic regimen dictated by the presence of an irremovable tumor mass. Fourteen of the patients received their first treatment at the Mayo Clinic. In 7 cases treatment instituted elsewhere was continued at the clinic because of neoplasms which had recurred.

Follow-up studies are available on 20 of these 21 patients and the detailed results are given in

Table I. Although we have no necropsy data on the 10 patients who have died, presumption that death was owing to the effects of carcinoma is afforded by roentgenograms positive for pulmonary metastasis in 5 of the group and of cervical nodal metastasis in 2 additional cases. The 5 patients who are living without any evidence of recurrence represent a disappointingly small group (25 per cent). The 2 deaths and the 2 recurrences in the group subjected to total parotidectomy make a poor showing for an operation of such magnitude. However, these 4 patients were suffering from very large infiltrating neoplasms. Paralysis of the facial nerve was present in 25 per cent of the patients on their first admission. It developed in an additional 43 per cent at a time following operation, which indicated a causation based on infiltration by recurrent tumor in all except the 3 cases in which the nerve was purposely sacrificed in the operative attempt to eradicate large tumors.

COMMENT

Although adenocarcinoma of the cylindroma type occurs in all locations which provide the tissue of origin for mixed tumors of the salivary glandular type, it is our firm opinion that there is no justification for including the two types within the same category. Histogenetically mixed tu-

TABLE I.—RESULTS OF TREATMENT IN CASES OF ADENOCARCINOMA CYLINDROMA TYPE OF THE PAROTID GLAND

Case	Treatment	Final results	Cases	Percent
	Palliative x-ray	Dead in 5 years		
	Palliative rx and radium	Dead in 5 years		
3	Local excision	Dead in 5 years

more arise from the epithelial cells of the salivary and lacrimal glands and also from mucous glandular elements of the lip, tongue, palate, larynx, and trachea. The tumors are well differentiated, often reproducing in fair detail the double layering of epithelium which characterizes the appearance of a normal salivary duct. A cartilage-like stroma is typically encountered. In adenocarcinoma of the cylindroma type ducts lined by double layers of epithelial cells are lacking the appearance being that of dark-staining honey-combed epithelial plugs. This may indicate as

suggested by Bauer and Fox, a derivation from the basal basket, regenerative or "invo-epithelial" layers of the glands and ducts of origin. Cartilaginous stromal changes are not observed but hyallinization of the stroma is of frequent occurrence.

Clinically location and duration are features which in a given case are by no means diagnostic of cylindromas as opposed to mixed tumor. The clinical incidence of pain, however, was 50 per cent in our group of cylindromas. In our series of submaxillary neoplasms pain had an incidence of 70 per cent as opposed to a 50 per cent incidence as a symptom of mixed tumor. Accordingly we feel that pain, especially of a sharp radiating nature is of importance in differential clinical diagnosis. Of parallel significance was the finding of fixation which in our experience was a noteworthy feature of cylindromas.

At surgical exploration cylindromas were found to be infiltrative in more than half of the cases and rarely in these cases was the surgeon satisfied that he had completely eradicated the disease. That his estimate was correct is attested by a recurrence rate of 75 per cent about three times the incidence for recurrence of mixed tumors (3). The question is therefore raised whether or not more radical surgical measures should not be undertaken for this more malignant cylindroma group. To most surgeons the mere mention of parotidectomy calls up at once the specter of a patient with severe facial palsy. However the analysis of this series reveals that almost one third of the patients had partial or complete paralysis of the homolateral facial nerve at the time of admission and this incidence reached two-thirds at the final analysis. That this figure is three or four times as great as the corresponding one encountered among patients operated on for mixed tumor (3) lends strong support to our pathologic observation that perineural involvement by tumor tissue rather than surgical trauma had been the factor responsible for the paralysis.

Admittedly if paralysis, complete or incomplete, of the facial nerve exists preoperatively it is due to the perineural invasion or pressure of the tumor.

If paralysis develops immediately after operation it is due to surgical interference with the nerve. This paralysis may be partial or complete. If it is partial it is usually due to tension or stretching of the nerve and slowly improves. If it is complete immediately the paralysis of the nerve is likely to be surgical and permanent. In a small percentage of cases, however complete paralysis may become partial and in a much smaller

number the patient may completely recover from it.

Paralysis developing a month or more after surgical resection can be safely attributed to incomplete eradication of the pathologic process and continued extension by infiltrating involvement.

Bailey has performed total parotidectomy for 7 parotid tumors with resultant palsy of the seventh nerve in 1 instance only demonstrating thereby that surgical interference with the nerve can at least occasionally be avoided.¹ In the 4 cases in which total parotidectomy was done in the present series the facial nerve had to be sacrificed because of large infiltrating neoplasms. Subsequent recurrence in all 4 cases and death in 2 of them indicated to us merely that the operation was too late rather than too little. It seems logical to assume that since resection of the gland although usually effective in the treatment of mixed tumors is followed in the cylindroma group by a 75 per cent incidence of recurrence, procedures at least approaching total parotidectomy should here be given a fair trial. We further feel that block dissection of cervical nodes on the involved side should be seriously considered. In this regard as mentioned in the foregoing the surgical pathologist familiar with the appearance of these tumors in fresh frozen sections can render a real service to his surgical colleagues.

While therapy with roentgen rays did not in the present series have any pronounced effect in the prevention or control of recurrences we feel that its possible benefits should never be denied to any patient suffering from this serious form of cancer.

SUMMARY AND CONCLUSIONS

1 Ten per cent of a series of consecutive primary parotid neoplasms appeared to be adeno-

M. Whorter showed that the human parotid gland consists of larger superficial and smaller deep lobe usually distinct and readily separable. The facial nerve and its branches lie between these lobes and not, as this the actual glandular substance. The two lobes are joined by an isthmus which separates the temporofacial and cervicofacial divisions of the main nerve trunk.

carcinomas of the type cylindroma so classified because of a distinctive microscopic pattern.

2 This group of 21 cases was characterized clinically by the presence of sharp radiating pain and local fixation of tumor in 40 per cent features unusual in connection with other primary neoplasms of this location. Partial or complete paralysis of the facial nerve was also a contrastingly common finding.

3 Surgically the tumors were generally more infiltrative than encapsulated and application of the principle of 'wide local excision' prevented recurrences in 5 of 21 cases.

4 Pathologically the appearance of dark staining epithelial islands and strands with central honeycombing in a hyaline stroma was diagnostic. Epithelial mucus was sometimes present. Infiltrative tendencies were pronounced with a special predilection for invasion of nerve sheaths.

5 Eight of the 20 traced patients succumbed within 5 years to the effects of metastasis, 5 with evidence of pulmonary spread. Two died more than 5 years after operation. Four of the remaining 10 are suffering from inoperable (?) recurrences.

6 Solid tumors of the parotid gland should be assumed to be malignant until proved otherwise.

7 It is suggested that more radical surgical procedures will have to be done in order to obtain better results in the treatment of this form of neoplasm.

A CLINICAL STUDY OF EARLY POSTOPERATIVE AMBULATION IN GYNECOLOGY

PAUL F. STEINHART M.D. Los Angeles, California

WITH surgical efficiency at its present level, we should not be satisfied merely with recovery from a surgical operation but we should know as Matas once stated how the patient has recovered, to what extent she has been restored to her anatomical and functional integrity to what extent she has been cured and made fit to return to her normal life and occupation how long it has taken her fully to recover after the operation and what are the end-results.

There is no excuse for leaving a single stone unturned to mitigate the suffering shorten the convalescence, and eliminate the economic waste incident to surgery on human beings (20) and, if early postoperative ambulation is an added means toward this end, then its use should be more widely adopted.

A comparison of the relative merits of early ambulation with those of late ambulation will be made in the following report. This presentation may in effect, along with similar preceding reports (17 22 23 25 27) remove prejudice and add to the surgeon's postoperative therapeutic armamentarium. Of course, there are limitations and although this series was consecutively treated by early ambulation, the surgeon's judgment should individualize each case. However the results demonstrate that fear of early ambulation is in the majority of cases, unwarranted.

PRESENTATION OF DATA

Fifty four consecutive cases are herewith discussed. The first 17 patients were maintained on the conservative regimen of late ambulation the following 37 patients received early postoperative ambulation. No attempt was made to collect additional cases of patients treated by the old regimen because it was desired to maintain the factor of the operator constant. Because of this fact no attempt will be made to quote percentages only a relative comparison will be made.

Since the original compilation of this report, several additional patients were also treated by early postoperative ambulation with apparently

similar results, but are not herewith included because of insufficient follow-up.

All patients were charity cases, from many sections of the State of Nebraska. All patients received adequate preoperative care. Patients with low blood counts and hemoglobin values received adequate transfusions.

The technique of operation was constant in both series.

Of the patients ambulated early 7 had Pfannenstiel incisions, the remainder had midline incisions. All of the patients ambulated late had midline incisions.

In all total abdominal hysterectomies, 5 grams of sulfathiazole powder or crystals was introduced into the abdomen prophylactically. In other cases, only in the presence of old infection was sulfathiazole powder or crystals used.

Abdominal closure was made by layers, the peritoneum was closed by a continuous stitch of No. 0 or No. 1 plain catgut the fascia was closed by a continuous stitch of No. 0 or No. 1 chromic catgut from each angle to the middle of the incision the skin was closed with fine dermal interrupted vertical mattress sutures. No tension sutures were used (except in the case of 1 patient because of obesity—weight 225 pounds—on whom an incidental incisional ventral herniorrhaphy was performed).

Spinal anesthesia was used in the majority of cases cyclopropane and ether were used when spinal anesthesia was refused. In a very few cases, the spinal anesthesia was supplemented with cyclopropane and ether near the close of the operation. One elderly patient aged 74 years, was operated upon under local anesthesia of 1 per cent novocain for the removal of a very large ovarian cyst a multilocular serous cystadenoma.

There were no postoperative dietary restrictions in either series. Diet was taken as tolerated liquids, soft or regular. Intravenous fluids were rarely administered immediately postoperatively and this treatment was carried out only if the operation was extensive. Fluids were usually taken orally.

A retention catheter attached to a bottle was used after all plastic operations and vaginal hysterectomies. In the patients ambulated early

From the Department of Obstetrics and Gynecology, University of Nebraska, College of Medicine, University Hospital, Omaha, Nebraska.

TABLE I.—EARLY AMBULATION

Type of operation	Pathology	No. cases
Total hysterectomy 3 cases	Fibromyomatous uteri Highly malignant sarcoma 1 case Adenocarcinoma of cervix Uterine bleeding, cause unknown	
*Subtotal hysterectomy 6 cases	Fibromyomatous uteri Chronic pelvic inflammatory disease	4
Laparotomy 3 cases (Incidental appendectomy as done in 8 cases)	Simple cystic ovaries Bilateral polycystic ovaries Multilocular serous cystadenoma of ovaries Right tubo-ovarian abscess and periappendicitis Retroverted uterus Scarred appendix and appendix vesicle	4
Vaginal hysterectomy and colpoperineoplasty 3 cases	Fibromyomatous uteri with cystocele Prolapsed uteri (2-3") with cystocele (1 patient had fibromyomatous uteri)	3
Plastic operation 7 cases (includes urethroplasty and Manchester opera- tions)	Marked cystocele Marked cystocele (fol- lowing total hysterectomy) Urethrocele and rectocele Prolapsed (?) of uterus with elongated cervix with cervical-cystocele	4
Combined abdominal and plastic operation cases	Marked cystocele with degrees prolapse and retroverted uterus Lacerated pelvic floor with chronic cervicitis and retroverted uterus	
Low cervical cesarean section case	Laceration, previous cesarean sections	

*Unilateral or bilateral salpingo-oophorectomy or incidental appendectomy were performed on some of these patients.

the catheter was kept in for the first 24 hours (except for 2 cases, one a vaginal hysterectomy performed on an obese patient weighing 217 pounds and the other a urethroplasty in which the catheter was kept in for 48 hours). In the patients ambulated late the retention catheter was used for 72 to 96 hours. In 3 total abdominal hysterectomies (2 in the early ambulated series and 1 in the late ambulated series) because some difficulty was encountered in the dissection of the bladder from the cervix a retention catheter attached to a bottle was used for the first 24 hours. In all other cases patients were catheterized only when necessary.

A study of the patients treated revealed the following salient features:

The age range of the patients treated by early ambulation was from 15 to 74 years of those treated by late ambulation 30 to 70 years. The mean age of those ambulated early was 41.2 years of those ambulated late 52.1 years. The weight range of the patients ambulated early was 110 to 225 pounds of the patients ambulated late

TABLE II.—LATE AMBULATION

Type of operation	Pathology	No. cases
*Total hysterectomy 3 cases	Fibromyomatous uteri Adenocarcinoma of uterus Uterine bleeding, cause unknown	
*Subtotal hysterectomy 4 cases	Chronic pelvic inflammatory disease Uterine bleeding, cause unknown Endometriosis of ovary with uterine bleeding, cause unknown Adenocarcinoma of ovaries with adenomyosis of uteri	
Laparotomy case	Bilateral prostatic	
Vaginal hysterectomy and colpoperineoplasty 4 cases	Prolapsed uteri 2-3 degrees with cystocele (one case of adenomyosis uteri) Complete procidentia uteri with marked cysto- rectocele	3
Plastic operation 3 cases (includes urethroplasty)	Marked cystocele (1 patient with elongated cervix, 1 with cervicitis requiring amputation) Urethrocele and rectocele	4

*Unilateral or bilateral salpingo-oophorectomy or incidental appendectomy were performed on some of these patients.

112 to 230 pounds. The nutritional status of the patients in both series was approximately the same.

In the early ambulation series, there were 2 patients with hypertensive heart disease, 1 with rheumatic heart disease, 2 with positive serology (Mazani) and 1 with chronic bronchitis. In the late ambulation series there were 3 patients with hypertensive heart disease and 2 with diabetes mellitus.

Wound healing was not affected by the positive serology or the diabetes mellitus in either series.

The surgery performed on the patients ambulated early included 5 total abdominal hysterectomies, 6 subtotal hysterectomies, 13 laparotomies for surgery other than hysterectomy, 3 vaginal hysterectomies, 7 plastic operations, 2 combined abdominal and plastic operations, 1 cesarean section (this case is included because of the abdominal surgery entailed). For the pathology associated with these cases see Table I.

The surgery performed on the patients ambulated late included 3 total abdominal hysterectomies, 4 subtotal hysterectomies, 1 laparotomy for surgery other than hysterectomy, 4 vaginal hysterectomies, 5 plastic operations. For the pathology associated with these cases see Table II.

The patients who were ambulated early wore tight abdominal binders and, in the majority of instances, got up in a chair on the first postopera-

Fig. 1. A composite graph of the temperatures and pulse rates of both series.

tive day with bathroom privileges. A few because of hesitation and fear dangled on the first day (8 out of 37 patients). All patients were up and about on the second day. Two patients who had undergone vaginal hysterectomies and 1 who had undergone a urethroplasty were ambulated on the second day because a retention catheter was used for the first 48 hours. Early ambulation was not insisted on but was encouraged. This series includes 4 patients, 3 of whom ambulated themselves on the third day, 2 of whom ambulated themselves on the fourth day. The majority of patients who were ambulated late got up in a chair on the seventh or eighth day, 1 patient got up on the sixth day, 1 on the tenth day and 1 on the twelfth day.

A composite graph of the temperatures and pulse rates of both series (Fig. 1) such as was presented by Powers in his report, shows relatively little significant changes due to early ambulation. Like that of Powers, these were plotted by averaging the highest levels recorded for every patient on each day and thus represent maximal elevations during the convalescent period.

Postoperative invalidism, both psychical and physical, was markedly reduced in the patients who were ambulated early. There was less apprehension on the part of the patient and the family as to the patient's condition and prognosis. There was a notable decrease of the usual postoperative complaints on the part of the patient. Nursing care requirements were markedly reduced.

The necessity for catheterization of patients with abdominal surgery occurred for the most

part on the operative day and the number of patients requiring catheterization was relatively the same in both series. Of the patients ambulated early 7 of the 35 abdominal cases required catheterization and this on the operative day. One patient only required a second catheterization on the first postoperative day. Of those ambulated late, 3 of the 8 abdominal patients required catheterization and this was necessary on the operative day only.

All the patients on whom plastic operations and vaginal hysterectomies were done, whether ambulated early or late, showed the same relative frequency of catheterization following removal of the retention catheter. Of the patients ambulated early 2 out of 12 required catheterization once; of the patients ambulated late, 1 out of 9 required catheterization once. The early ambulated patients, however emptied their bladders more completely suggesting that in these types of operation there was an earlier return of bladder tonicity with early ambulation. Although a study of residual urine was not carried out in all cases due to a shortage of nurses, the findings in the cases in which this study was done seemed to confirm this fact. A more complete study of all the cases, made by averaging the lowest quantities of urine voided, the highest quantities voided and the frequency of voiding for the first 3 days following removal of the retention catheter revealed that the patients who were ambulated early voided larger quantities and less frequently (Table III).

In both series there were a few patients who were able to move their bowels without the aid of

hematoma however the incidence was greater among those who were ambulated early (14 of the 17 patients ambulated early compared with 2 of 17 patients ambulated late). There were no cases of abdominal distention in the patients who were ambulated early and only 1 case of moderate distention in the patients who were ambulated late.

The requirements of sedation during the operation were comparatively the same in both series. After early ambulation sedation was rarely required.

The number of hospital days here reported is not necessarily a true indication of the hospital days required for convalescence. Since patients came from many sections of the state and in many cases were required to travel great distances, discharge from the hospital was made according to the convenience of the patient and not necessarily at the time when the patient was physically able. Some patients stayed as long as 2 to 5 days beyond the time of discharge. Because this factor was constant in both series, the relative number of hospital days saved is still quite evident. The average number of hospital days required by the patients who were ambulated early was 8.72 days as compared with 13.94 days required by the patients who were ambulated late. Early ambulation therefore, saved an average of 5.22 hospital days per case. A comparison of the type of hospital days required according to the type of operation performed is given in Tables IV and V.

The patients ambulated early developed the following postoperative complications: unexplained fever 2 cases, acute bronchitis, 1 case, phlebitis, 1 case, hematoma in incision 1 case, phlebitis, 1 case, hematoma in incision 1 case.

Unexplained fever occurred during the postoperative course of 2 patients, one upon whom a hysterectomy had been performed and the other a plastic operation. Physical examination and laboratory findings were negative in both cases.

Acute bronchitis occurred in a patient weighing 217 pounds, with known chronic bronchitis, on whom a vaginal hysterectomy was performed. The patient had a predisposing focus of infection and it is possible to conceive that early ambulation in this very obese patient prevented the possibility of bronchopneumonia.

Phlebitis occurred in a patient on whom a urethroplasty was performed. Early ambulation in this patient was evidently insufficient prophylaxis against this attack of phlebitis. It may be noted that this patient had a milk leg in the opposite leg 20 years ago following a normal delivery.

TABLE III

Patients	Lowest quantity voided Ounces	Highest quantity voided Ounces	Frequency per day
Ambulated early	5 (50 c.c.)	3 (500 c.c.)	4
Ambulated late	4 (50 c.c.)	(500)	6

A hematoma in an incision occurred in a patient who had a Gilliam suspension. The hematoma was at the level where the round ligaments were anchored to the fascia and evidenced itself by a 1 inch gape of the incision on the sixth postoperative day. While this hematoma may be attributed to early ambulation it is conceivable that a small unrecognized bleeder may have been produced at the time of operation in one of the perforations of the fascia and recti muscles through which the round ligaments were drawn. The patients ambulated late developed only 1 postoperative complication: 1 case of unexplained fever. Unexplained fever occurred after operation in a patient who had undergone a vaginal hysterectomy. Physical examination and laboratory findings were negative.

The follow-up on these patients revealed that the convalescent period at home was much less for those patients who were ambulated early. Of the patients ambulated early 8 were able to resume their normal activities immediately after leaving the hospital of those who were ambulated late only 1 was able to do so. The average convalescent period at home required by the patients who were ambulated early was 3.87 weeks, compared with 6.5 weeks required by those who were ambulated late. The average total convalescent period required by those who were ambulated early was therefore 3.3 weeks less than that required by those ambulated late. The duration of convalescence according to type of operation is shown in Tables IV and V.

A follow up of both series, over a period of 6 to 8 months, has revealed no disruption of wounds, no incisional ventral hernias, no recurrent cystoectoceles, no prolapse of the vault of the vagina following vaginal hysterectomies.

DISCUSSION

The above data reveal certain obvious clinical advantages in early postoperative ambulation. A study of the etiology and pathology of postoperative pneumonia, atelectasis, embolism in the lungs, phlebotrombosis, etc., indicates that early ambulation also offers advantages in the prophylaxis of these conditions.

With the patient on her back following surgery the stage is set for many hours of recumbency with

TABLE IV—EARLY AMBULATION

Type of operation	Hospital days (Average) Days	Convalescent period home (Average) Days	Total convalescent period Days
*Total hysterectomy	9.2	29.4 (4 weeks)	38.6 (5.6 weeks)
**Subtotal hysterectomy	8.6	8 (1 weeks)	16.6 (2.4 weeks)
Laparotomies	7	20.0 (2.8 weeks)	27.0 (3.9 weeks)
Unilateral hysterectomy and colporrhaphy		21.2 (3.0 weeks)	28.2 (4.0 weeks)
***Plastic operations		25 (3.6 weeks)	32 (4.6 weeks)
Combined abdominal and plastic operations	9.5	22 (3.1 weeks)	31.5 (4.5 weeks)
Low cervical cesarean section	9	25 (3.6 weeks)	34 (4.9 weeks)
All types averaged in total	8.7	27.0 (3.9 weeks)	35.7 (5.1 weeks)

*Unilateral or bilateral salpingo-oophorectomy or incidental appendectomy were performed on some of these cases.

†Number of hospital days recorded are not necessarily the actual number of hospital days required—frequent home transportation difficulty.

**1 case complicated, requiring 3 days is not averaged.

shallow breathing (4, 25). There is a pooling of the tracheobronchial secretions in the finer ramifications of the bronchial tree and very often a disinclination to cough due to pain. This, in association with the limitation of the respiratory excursions, allows for an obstruction in the distal bronchioles. The free drainage by which the lung is kept in an aseptic condition is interfered with the air distal to the obstruction is absorbed the corresponding lobules collapse and in the occluded area, with a predisposing infection, a mild pneumonia may develop.

The increased lung expansion afforded by the exercise of early ambulation would no doubt aid in the prevention of the pooling and stasis of the tracheobronchial secretions, and hence early ambulation should be definite prophylaxis against such pulmonary complications.

The metabolism (7) and muscle tone of the recumbent patient are low. There is a decrease in the volume of flow in all the vessels of the body. The venous pressure is low and the caliber of the

veins, especially in the abdomen, pelvis, and legs, is much smaller than when sitting up. Only when the patient is sitting or standing are these veins constantly dilated. Frykholm suggested that collapsed veins may have endothelial damage, predisposing to later thrombosis. Veins, which are compressed and empty due to pressure of the legs against the bed as suggested by Dock, may easily suffer endothelial damage and begin to thrombose while nearly empty. Dock further pointed out that phlebotrombosis may begin in the venules of the muscles and subcutis, or in the pelvic venous plexuses where complete stasis is possible. The formation of large clots propagated far along the system is made possible by prolonged recumbency. The dislodgment of clots with the formation of emboli is effected when after this prolonged recumbency there is a sudden rise of venous pressure such as is produced by getting out of bed or straining on a bed pan.

Pulmonary embolism has always been a by-product of surgery especially in gynecology and

TABLE V—LATE AMBULATION

Type of operation	Hospital days (Average) Days	Convalescent period home (Average) Days	Total convalescent period Days
*Total hysterectomy	5	36 (5.1 weeks)	41 (5.9 weeks)
**Subtotal hysterectomy	3	00	00
Laparotomies		22 (3.1 weeks)	25 (3.6 weeks)
Unilateral hysterectomy and colporrhaphy	12.5	20.0 (2.8 weeks)	32.5 (4.6 weeks)
Plastic operations	8	26 (3.7 weeks)	34 (4.9 weeks)
All types averaged in total	7.94	23.5 (3.4 weeks)	31.4 (4.5 weeks)

Unilateral or bilateral salpingo-oophorectomy or incidental appendectomy were done in some of these cases.

†Number of hospital days recorded are not necessarily the actual number of hospital days required—frequent home transportation difficulty.

**Of cases—reported immediate resumption of usual activities; failed to report—were fully active at the end of 2 weeks and with delayed advancement of exercise with assistance, as well as arrived at 7 weeks. Therefore the average convalescence could not give true average for the period of convalescence for that type of surgery.

obstetrics. It may occur suddenly in uncomplicated cases of patients who have progressed satisfactorily. The patient is allowed up out of bed for the first time on the seventh day or later and like a bolt out of the blue, a fatal embolism occurs. Fortunately this accident is not very frequent however when it does occur it is grim tragedy.

Since muscular activity increases the venous circulation of the lower extremities, walking would prevent stasis in the venules of the muscles also since sitting or standing increases the caliber of the pelvic veins, stasis in the pelvic vessels associated with recumbency is thus removed. The prophylaxis afforded by early postoperative ambulation against such postoperative accidents should be quite apparent.

Early postoperative ambulation in plastic operations and vaginal hysterectomies causes no additional pain or discomfort. Patients who were ambulated early felt much more comfortable and invalidism was greatly decreased. Pain on sitting in a chair is avoided by the use of an inflated rubber cushion ring.

There may be some pain in the incisional area of abdominal operations on the initial attempt to arise, but this quickly subsides. The patients then feel more comfortable and from then on they have very few if any complaints about pain. Patients who had previous laparotomies in which they had been treated by the conservative regimen of late ambulation themselves volunteered the information that with early ambulation they had less discomfort and very little pain.

It has already been stated that a follow up of the patients treated by early postoperative ambulation in this report has revealed no wound disruptions, no incisional ventral hernias, no recurrent cystoceles, no prolapse of the vault of the vagina following vaginal hysterectomies and a study of the etiology of these conditions suggests no reason why early postoperative ambulation should result in a greater incidence of these conditions.

The breakdown of plastic operations or the prolapse of the vault of the vagina following vaginal hysterectomies may be entirely attributed to poor surgery or poor tissue, fascia etc. or both. Recurrent cystoceles or prolapse of the vault of the vagina following vaginal hysterectomies are seen frequently in patients who were ambulated late. Anatomically it is not conceivable that walking or sitting produces any significant stress or strain on the fascial supports of the bladder or rectum or the uterosacral and round ligaments which are used to support the vault of the vagina.

following vaginal hysterectomies. A cough or a sneeze in bed would cause more strain by the increased intra abdominal pressure thereby produced than would walking or sitting.

R A Cutting wisely stated that if unusual strains were a frequent cause of wound rupture the condition might well be expected to occur with a far greater degree of frequency than it does, because even though unusual strains be construed rather narrowly such strains occur far more frequently than wound rupture.

Brettner in 1899 was the first to describe wound disruption in the American literature, with a report of 3 cases. Several large series (3 8 10 11 12 21 24 28 29) have since then been reported. One is impressed with the variety of opinions as to etiology. There are many predisposing and precipitating factors suggested as being responsible for wound disruption.

The salient predisposing causes as evidenced by the many reports in the literature include the following obesity or asthenia (28) malnutrition (28) hypoproteinemia (13 15 26 28 30), avitaminosis (13 28) low ascorbic acid level (13 28 32) dehydration (28) diabetes mellitus and similar disturbances of sugar metabolism (32) malignancy (28) especially if previous radiation has been given and presence of acute or chronic pelvic inflammation (28).

The technique of wound closure is of obvious importance and various factors have been emphasized. Many have stressed in the technique of wound closure the significance with respect to the careless hemostasis (14 16) too tight suture of the fascia (6) the grasping of large masses of tissue in ligatures (18) excessive use of catgut (1) etc.

The salient precipitating factors, as evidenced by the many studies of evisceration are all conditions which increase the intra abdominal pressure (11 12 24 28 29). These include abdominal distention, with severe coughing or persistent emesis, hiccoughing etc.

The etiology (6 18, 19) of postoperative incisional ventral hernia is similar to that of wound disruption. Here, too poor operative technique and postoperative complications, such as abdominal distention associated with vomiting coughing and hiccoughing are stressed.

Considering all these factors, it is difficult to conceive that wound disruption or incisional hernia should occur more frequently with early postoperative ambulation than those treated by late ambulation. Predisposing causes of wound disruption or incisional ventral hernia such as malnutrition hypoproteinemia avitaminosis

scurvy (low ascorbic acid level) dehydration and so on should be eliminated by good preoperative care, a recognized necessity for all surgery. The importance of good operative technique in abdominal closure is taken for granted whether the patient is ambulated early or late. Should abdominal distention occur as a postoperative complication the surgeon's judgment should of necessity forbid the continuation of early postoperative ambulation, if already instituted, and appropriate measures should be taken to treat the cause of the distention.

It is interesting to note that in many reports in the literature, the incidence of wound disruption appears to be approximately the same as the incidence of fatal pulmonary embolism following surgery. In a study of wound disruption Schmitz and Beaton found an incidence of 0.18 per cent, Glenn and Moore (10) 0.66 per cent, Norris, 0.5 per cent, Singleton and Blocker 0.67 per cent, Barker *et al.* in a statistical study of pulmonary embolism, found that the incidence of fatal pulmonary emboli, associated with major gynecological surgery, ranged from 0.53 to 0.73 per cent. The mortality rate of wound disruption, however, appears to be at least 50 per cent less than that of pulmonary embolism. Bowen found that the mortality rate of wound disruption ranged from 16 to 75 per cent. The average reported mortality rate of wound disruption according to Schmitz and Beaton is 34.8 per cent. It seems logical, therefore, to employ early postoperative ambulation as prophylaxis against pulmonary embolism in spite of fear of wound disruption, which is unwarranted as has been indicated.

SUMMARY

Fifty four consecutive cases are reported the first 17 cases were maintained on the conservative regimen of late ambulation, the following 37 cases in the group received early postoperative ambulation.

1. The temperature and pulse rates showed relatively little significant change due to early ambulation.

2. Postoperative invalidism, both physical and physical, was markedly reduced in those patients ambulated early.

3. The nursing care requirements were markedly reduced.

4. No significant difference was noted in the requirements of postoperative catheterization in abdominal cases. In plastic operations and vaginal hysterectomies, however, an earlier return of bladder tonicity was suggestive in those patients ambulated early.

5. Those patients ambulated early were relatively more able to move their bowels without the aid of an enema.

6. Sedation was rarely required after patients were ambulated early.

7. The average number of hospital days required by the patients ambulated early was 8.71 days, by those ambulated late 13.04 days, thus saving an average of 5.32 hospital days per patient for those who were ambulated early.

8. The average convalescent period at home required by the patients ambulated early was 3.7 weeks by those ambulated late 6.5 weeks. The average total convalescent period required by those who were ambulated early was 3.3 weeks less than that required by those ambulated late.

9. A study of the etiology and pathology of postoperative pneumonia, atelectasis, pleurothrombosis, embolism, and infarcts indicates that early postoperative ambulation also offers advantages in prophylaxis.

10. Pain and discomfort as a result of early postoperative ambulation were not in evidence in this series. In fact, the patients who were ambulated early had less pain and discomfort than those who were ambulated late.

11. Early postoperative ambulation in plastic operations and vaginal hysterectomies should result in no greater incidence of recurrent cystoceles or prolapse of the vaginal vaults following vaginal hysterectomies. Anatomically there is no evidence of added significant stress on the fascial and ligamentous supports from early ambulation.

12. A study of wound disruption and incisional hernia suggests that early postoperative ambulation should not in itself result in a greater incidence of wound disruption and incisional hernia providing, of course, the patient has received good preoperative care and the usual good operative technique.

13. Follow-up in this series revealed no wound disruptions, no incisional hernias, no recurrent cystoceles, and no prolapse of the vaginal vaults following vaginal hysterectomies.

CONCLUSIONS

Early postoperative ambulation in gynecology reduces the usual postoperative invalidism, both physically and physically and results in a more rapid convalescence. Gastrointestinal and bladder tonicity may be increased. Very little, if any sedation is required after early ambulation is instituted. Nursing care is markedly reduced. There is an increased economy for the patient.

There is a definite advantage in early ambulation as prophylaxis against postoperative post-

monia, atelectasis, phlebothrombosis embolism and infarcts. Early postoperative ambulation *per se* should in no way increase the incidence of wound disruption, postoperative incisional hernia, recurrent cystoectoceles following plastic operation or prolapse of the vaginal vault following vaginal hysterectomies.

IPSILATERAL SPASTIC RECTUS ABDOMINIS IN A PURELY THORACIC WOUND

OBSERVATIONS on wounds of the thorax within the first few hours after injury have yielded some interesting side lights on these dangerous wounds. In one action resulting in 250 deaths on the battlefield 60 deaths or approximately 25 per cent were due to wounds involving mainly the chest. Death from chest wounds on the battlefield or at the forward dressing station occurs most frequently due to massive hemorrhage from injuries to the heart the aorta the vena cava the hilar vessels or even to the subclavian vessels running over the apex of the lung. If the wounded man survives the threat of immediate hemorrhage and can be transported to an evacuation hospital his chances for survival are greatly increased but even here death from exsanguination may still occur although in decreasing numbers as pooled universal group O blood

and massive transfusions are made as readily available as plasma.

A second cause of early death is a tension pneumothorax incident to a laceration of the lung or of a bronchus, which may open as the lung relaxes in expiration. The obvious dyspnea the immobile but distended hemithorax the resonance on percussion and absence of breath sounds, give clear evidence of the need for prompt withdrawal of air but not infrequently the need for the continuous escape of air is unrecognized and death from respiratory and circulatory failure occurs. A patient who has had one aspiration for a tension pneumothorax with removal of apparently sufficient air to correct the mediastinal displacement must be under careful and repeated observation for the next 48 hours lest a recurrence of the pneumothorax be overlooked. The introduction of a needle or of a catheter into the chest for the continuous escape of air should not be approached with timidity even by surgeons inexperienced in thoracic work. If an underwater seal or a flutter valve is also provided, one need have no hesitancy in producing such a temporary opening into the thoracic cavity.

A fascinating but poorly understood early observation in connection with wounds limited to the chest has been an accompanying abdominal wall rigidity usually unilateral, occasionally bilateral and often associated with subcostal tenderness on palpation and percussion strongly suggesting an intra-abdominal injury. There is also absence or markedly reduced amplitude of excursion of the abdominal wall during respiration suggesting an immobile or spastic diaphragm or even an

underlying peritonitis. Frequently these signs are present only in the early hours after injury, they disappear spontaneously some times within 18 hours and they rarely persist more than 48 to 72 hours. In the first few hours after injury they may be so pronounced that one might easily be tempted to perform an abdominal exploration for a ruptured viscus.

Occasionally in association with through and through wounds of the lower right chest, the right diaphragm and dome of the liver may sustain an injury which is quite unsuspected before its disclosure at operation or at autopsy with a resulting rigidity of the abdominal wall and tenderness of the entire abdomen due to the irritating effect of bile and blood in the peritoneal cavity.

It is not uncommon of course, to find such abdominal spasticity and subcostal tenderness on the same side as a lower lobe pneumonia attributable to involvement of the diaphragmatic pleura in the inflammatory process. In the cases under discussion there was no injury to the diaphragm and no inflammation except that incident to blood in the pleural space. In one case autopsy served to illustrate the frequently observed phenomenon of a spastic abdomen associated with injuries entirely limited to the chest.

A number of nonfatal cases could be cited illustrating the effect upon the abdominal wall of purely thoracic injuries. Conversely similar phenomena involving the uninjured chest, consecutive to wounds of the abdomen have also been observed. What operator has not noted following a McBurney incision or a right rectus incision or a wound of the flank, a definite lag in respiration, a limitation in the excursions of the chest and diminished breath sounds on the side of the wound even with no evidence of bronchial obstruction or atelectasis to explain it?

In one instructive instance three observers independently concluded that a private with a large left flank wound draining feces through a tangential laceration of the colon had a left subphrenic abscess due to high fever, diminished respirations, faint breath sounds, dullness suggesting a high diaphragm and tenderness on heavy percussion of the left lower chest. When no pus was found on aspiration at several points the wound itself was widely opened, and a large piece of shrapnel and sequestered bone were removed from a lumbar abscess followed by complete disappearance of all chest signs.

A connecting link between the two serous lined cavities is the sympathetic chain but the mechanism whereby it acts is unknown due to our limited knowledge of the sympathetic pathways and the direction of their impulses. The intercostal nerves may be part of a reflex arc capable of mediating painful stimuli from the site of injury and affecting the abdominal wall innervated by them. A third possible explanation lies in the irritating effect of free blood in the pleural space upon the parietal and diaphragmatic pleura and upon structures which are unaccustomed to its presence. The early disappearance of this effect may be the result of dilution of the blood through pleural weeping. Whatever its explanation this highly interesting reciprocal relationship between the two major serous lined cavities of the body and how it is mediated should yield to carefully planned experimentation.

Surgeons generally should be aware that in the presence of a chest wound, a spastic tender abdomen does not necessarily require a laparotomy and if clinical and x-ray studies definitely disclose that the missile in its line of flight did not traverse the abdomen or its parietes one may safely disregard the abdominal signs.

EMIL HOLMAN

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE book by Clement A. Smith, *The Physiology of the Newborn Infant* is a monograph which deserves more than passing notice. Pediatricians and obstetricians particularly will find it useful. Lack of a source book of information on this subject has long been felt. New clinical observations and scientific research during the last few years have added much to knowledge in this field and have made all previous accounts of neonatal physiology obsolete. The present text assembles these data.

The text concerns itself with the period of the newborn and its transition from fetal life. The subjects of respiration, circulation, blood, metabolism digestion, assimilation renal physiology endocrinology and immunology are treated. Thus it is quite a complete treatise of neonatal physiology with the exception of the nervous system and sense organs. The author states that the absence of the section devoted to the nervous system is not an oversight most of the available knowledge upon that subject, he points out, is limited to the fetus or is anatomical in nature or considers the newborn period only briefly in relationship to general neuromuscular development. It is indeed true that physiology of the nervous system at the time of birth and during the first few months of life is a *terra incognita*.

The author himself has contributed scientifically to a number of the subjects dealt with in his book. Thus he writes with great insight. The reviewer was especially pleased with the chapters on respiration and circulation. However each succeeding chapter of the book is so full of new and important information that it seems more important than the preceding one. None is dull each makes good reading.

One of the outstanding features of Professor Smith's monograph is the presentation at the conclusion of each chapter of a clinical summary in which the scientific data are discussed briefly from the standpoint of practical medicine. It is these summaries which make the book so useful to the clinical reader. Another interesting summary is found in a table printed on the back inside cover. This is a table of normal values at birth and on succeeding days thereafter. It serves as a ready and handy reference synopsis. Excellent bibliographies appear at the end of each chapter.

The Physiology of the Newborn Infant is very attractively printed and bound. It is not a large book. The text including the index occupies only 312

pages. Great credit is due the author for getting into such small volume so very much useful and interesting material.

WILLIAM F. WOOD.

THE third edition of *Fractures of the Jaws* by Ivy and Curtis² will be received with proper appreciation by all who have to deal with maxillofacial surgery. The writing is clear and concise, and the subject matter carries the authority based on years of personal experience. The authors describe their own successful methods and also those of contemporaries in a generous manner. The character of the text remains the same, however various new techniques and methods of fixation have been added.

We would particularly draw attention to the sections on roentgenographic technique and dietary management. These two important adjuncts to the successful treatment of jaw fractures cannot be too highly commended. Proper attention to these precepts will facilitate reduction of the fracture and recovery of the patient.

This compact book is well and profusely illustrated and it is a pleasure to suggest that every dentist, maxillofacial and general surgeon would profit by adding it to his library to read, study and have available for ready reference.

FREDERICK W. MURPHY.

THE *Primer of Electrocardiography*³ by George Burch, M.D., and Travis Winsor, M.D. describes in detail the fundamentals of electrocardiography. In the strict sense the title is somewhat misleading for the book goes into more detail than the word 'primer' would lead one to believe. On the other hand, the authors probably felt that this was apropos inasmuch as only the basic considerations of this diagnostic procedure were covered. Through the liberal use of diagrams, each point is adequately exemplified. The theories of electrocardiography, precordial leads, and diseases of the heart beat are well covered. The chapter on the clinical significance of the various components of the electrocardiogram is well written and will be of definite value to the beginner. It will also serve as a handy reference to those who are more thoroughly versed in electrocardiography as it contains many details which cannot be found in books stressing interpretation. Although no photographs of actual electrocardiograms are included the important

¹FRANCHESCHI OF THE JAW By Robert H. Ivy, M.D. D.D.S., F.A.C.S. and Lawrence Curtis, A.D. M.D. D.D.S. F.A.C.S. 3rd ed. Philadelphia: Lea & Febiger 1942.

²A PRIMER OF ELECTROCARDIOGRAPHY. By George Burch, M.D. F.A.C.P. and Travis Winsor, M.D. Philadelphia: Lea & Febiger 1941.

³THE PHYSIOLOGY OF THE NEWBORN. By Clement A. Smith, M.D. Springfield, Illinois: Charles C. Thomas 1943.

changes occurring in various types of heart abnormalities are adequately demonstrated. When used in conjunction with a manual stressing interpretation it should prove helpful in the study of electrocardiography.

T. R. VAN DELLEN

THE second edition of a very clear and practical book on *The Intervertebral Disc* by Bradford and Spurling brings up to date our knowledge of this subject and places special emphasis on the clinical and neurological diagnosis of herniation of these discs. Growth and mechanical factors are discussed in the first chapter with emphasis on the great anterior hydraulic compressive force placed upon the nucleus pulposus of the fourth and fifth lumbar discs in forward lifting strain. Pathology associated with age change is considered an important factor in disc herniation although sclerosis, narrowing and vertebral hypertrophic changes are not commonly related to nucleus pulposus herniation.

The clinical study of patients with "low back and sciatic pain" is very well presented except that there is continued confusion in reference to pain or "sciatica" along the course of the great sciatic nerve and lack of clear definition of symptoms and signs of single nerve root distribution. It is regrettable that these authors who have been leaders in the emphasis of neurologic diagnosis and unnecessary use of the spinoqram should be unable to present any consistent dermatome pattern in the lower extremity and continue to use the somewhat untimely and authoritative Tilney and Riley for illustrations of dermatome patterns. These charts were taken from Dejerine (1914) without any very evident original work to support them, and certainly are outdated by the more authoritative work of Foerster (1933). The irregularity of the areas of hypesthesia in clinical cases illustrated in this book denotes inaccuracy of technique in plotting these areas. Also there are conflicting statements about the occurrence of sensory loss in association with single nerve root involvement the authors tending to adhere to Foerster's dictum that this does not occur but citing a high percentage (75 per cent) of detectable hypesthesia in proved herniated nucleus pulposus cases with admitted single nerve root involvement. Better technique is needed on this subject as others are able to outline consistent diagnostic areas of dermatome hypalgesia from unquestionable single nerve root loss.

The roentgenological presentation calls attention to the usual lack of diagnostic findings of herniation of the nucleus pulposus except by myelography or the spinoqram. The authors very properly reserve the use of the spinoqram to atypical or doubtful cases in which localization cannot be made by history and neurologic signs calling attention to the possible complications and uncertainties of intraspinal foreign media.

1. INTERVIEW BY AL. HING, WITH SPECIAL REPORTS BY TO. RUTHERFORD OF THE ARMY, 1. 1900. WITH 11 ILLUSTRATIONS OF THE SPINOGRAM. BY F. K. B. BRADFORD, M.D. and R. G. SPURLING, M.D. 1940. Springfield, Illinois: Charles C. Thomas. 945.

Distinction is made in the application of manipulation therapy. It often being beneficial in early cases with predominant midline low back pain but liable to do harm in longer continued cases with entirely lateralized nerve root pain indicative of irreducible herniation. These latter cases may improve under long continued conservative rest or orthopedic treatment due to subsidence of acute swelling or in a destroyed insensitive nerve root. Surgical treatment by very limited hemilaminectomy carries less than 1 per cent risk does not significantly weaken the supporting structure of the back and offers immediate relief of the lateralized nerve root pain. A more conservative attitude is held when low back pain predominates as spinal fusion then may be necessary. Single nerve root section may be done to free a nerve from fibrotic adhesions and leaves no disabling functional loss.

The final discussion is interesting in the critical analysis of other reports. The authors consider it now well established that total involvement of either the 5th lumbar or 1st sacral nerve will usually produce objective sensory changes contrary to Foerster's dictum, while on a later page they state involvement of only one nerve does not often produce hyperesthesia. Dandy's contributions on concealed discs and surgical excision of discs are considered not well founded. Primary sciatic neuritis and sacral strain are called clinical curiosities. Kelgren's dermatome pattern of referred pain from interspinous ligament injection is commended for its dermatome localization but on the preceding page the authors state that localized pain is not very reliable in identifying the roots involved by herniation of nucleus pulposus. The orthopedic idea that narrowing of the 5th lumbar intervertebral foramen commonly causes nerve root pain is negated by the usual finding of a herniated nucleus pulposus compressing the 5th nerve root when symptoms of this root involvement are present. It is stated that there can be no doubt that the incidence of anomalies is greater in a series of patients complaining of low back and sciatic pain than in a control series. Inasmuch as this condition seems to predispose to nucleus pulposus herniation although in itself does not cause nerve root symptoms.

Cervical herniations are presented somewhat briefly but with emphasis on the recent establishment of small lateral herniation in the lower cervical region as a common cause of pain radiating from the neck over the shoulder and into the arm and hand with subjective sensation of paresthesia or numbness. As in the leg the pain and numbness follow a compressed single nerve root distribution and hypalgesia or hypalgesia may be demonstrated. Surgical relief can be given, as in the lumbar herniation after trial of conservative measures. Occasionally will cause herniation of annulus as well as nucleus will cause cord or cauda equina compression and demand prompt relief by surgical procedure.

J. JAY KEEGAN.

THE author of *Acute Injuries of the Head* is one of the leading neurosurgeons of England. By training surgical background, and large personal experience in the field of craniocerebral injuries he is thoroughly qualified to write on the subject of head injuries.

The book is addressed to the general practitioner and the general surgeon whom the author regards as vital links in the care of patients with cranial injuries. The subject of craniocerebral injuries has been covered from every angle in this book. The chapters on the mechanisms of injury and pathology are splendid. Those portions of the book describing technical procedures and operations are clearly written and generously illustrated. Posttraumatic sequelae are thoroughly dealt with. The author has given very thoughtful, realistic discussion of the organic and the functional factors contributing to the typical postconcussion syndrome with helpful guides for expressing the relative rôle played by these two factors in any patient. Principles of treatment described in the book will have the approval of most neurosurgeons. This reviewer differs with the author's opinion regarding the value of subtemporal decompression and repeated spinal drainage in the treatment of closed head injuries but it must be recognized that these are still unsettled issues. The author's style of writing is pleasing and invites further reading. He tends to avoid generalizations and prefers to make his points by numerous well chosen illustrative case records.

If any criticism were to be made of the book it would be in regard to the arrangement of subject matter. The book might be improved a bit, in the reviewer's opinion, by a change of certain chapter headings. For instance, Chapter III which is titled "Diagnosis" might better be titled "Clinical Manifestations and Typical Clinical Syndromes." Again, the arrangement of subject matter might be improved in one or two places. For instance, the chapter on pathology deals only with pathology of cerebral injuries, whereas the pathology of cranial fractures is dealt with in a subsequent part of the book, describing the treatment of these fractures. At another place in the book, under the subject heading of "Spinal Puncture," the author digresses far enough to discuss treatment of primary shock, transfusion, the management of associated visceral wounds, and the excision of compound fractures. At another place in the midst of a chapter on diagnosis the author consumes one full page in discussing the indications for subtemporal decompression. The discussion itself is entirely proper but the place in which the author has introduced it in the book appears to me untimely.

These are of course minor considerations judged against the general excellence of the subject matter and can be corrected in subsequent editions. The book is of comfortable size and pleasant to handle.

ACUTE INJURIES OF THE HEAD, THIRD EDITION, T. KENTWORTH COOPER, THOMAS W. BRIDGES, BY G. F. ROBERTSON, M.Sc. (Manc.) F.R.C.S. (Eng.). Foreword by Norman M. Dott, M.B. Baltimore, Md. Williams & Wilkins & Co. 1945.

Paper and printing are good. Illustrations are numerous and excellent. The author in his preface to the second edition, says "I believe that any general practitioner will find perusal of this book not only valuable, but will find the subject interesting and even exciting. With that opinion, I concur."

JOHN E. SCARRY

THE fourth edition of Kuntz' *A Textbook of Neuroanatomy*¹ follows the traditional pattern of introducing the gross topography of the nervous system with comparative and embryological sections then of reviewing the histology of nervous tissue and proceeding from peripheral nerve into the spinal cord to mount by several stages through the brain stem and emerge at the cerebral cortex. Within the limits imposed by such a repeated approach, in which, for example, consecutive chapters are devoted to nuclear connections of the cranial nerves, the cerebellum, the diencephalon, the optic connections and the autonomic nervous system, the author presents a clear description of neuroanatomy without excessive detail and with a concise summary at the end of each chapter. This last unusual feature will doubtless be greatly appreciated by the hard pressed medical student of today.

Passing reference to the functional and clinical significance of structures is made throughout the text and an entire chapter is devoted to that of the cerebral cortex. A laboratory guide is appended, together with a series of case histories illustrating the clinical aspects of injuries to the peripheral nerves, spinal cord and brain. Because all the brain lesions resulted from vascular disturbance the student may wonder why no reference to the blood supply of the nervous system was incorporated in the text.

H. W. MASON

IN the third edition of Kuntz' *The Autonomic Nervous System*² presentation of the general anatomy and physiology is succeeded by detailed discussions of the innervation of each of the organs, visceral pain, histopathology, disease, and autonomic neurosurgery. Specific citation of original articles is a constant feature and the one hundred twenty pages of assembled references constitute a unique bibliography in the many aspects of this field.

In the preface mention is made of the temptation to give undue weight to recent contributions that is resisted in varying degrees to preserve a balance between the new and the old. The reviewer is one who would like to have seen this resistance relaxed in the discussion of such topics as the terminal reticulus and ground plexus and the sympathetic innervation of skeletal muscle.

The book is recommended as a valuable reference work to everyone interested in the autonomic nervous system.

H. W. MASON

A TEXTBOOK OF NEUROANATOMY. By Albert Kuntz, Ph.D. M.D. 4th ed. Philadelphia: Lea & Febiger, 1945.

THE AUTONOMIC NERVOUS SYSTEM. By Albert Kuntz, Ph.D. M.D. 3rd rev. ed. Philadelphia: Lea & Febiger, 1945.

THE work described in *Pulmonary Tuberculosis in the Adult* by Max Pinner¹ is a welcome addition to the tuberculosis literature. The material has been wisely selected from the welter of divergent viewpoints and connected or really folded into a unit that is clearly presented easy to read and understand, and one that compels an absorbing interest in the subject.

Doctor Pinner states in the preface that he does not pretend to have written a textbook or a guide to treatment or diagnosis, but aims more to stimulate interest in the form of an introduction to the dynamic process of tuberculosis. His purpose has been fully realized. In addition to the many fascinating essays on the disease the author has given a valuable collection of short abstracts of important articles on the various topics.

No worker in tuberculosis or chest diseases should be without this book, although the work does not save, nor pretend to have anything but general usefulness for the surgeon.

The illustrations are adequate properly chosen and well reproduced. The type, printing paper and binding are worthy of the high standards already set by the publisher.

HENRY C. SWANBY

THE third revision by Stander of *Textbook of Obstetrics*² represents the ninth edition of *Williams' Obstetrics* but it is published under the present author's name since, as he states in the preface it embodies his teaching and practice and therefore he assumes full responsibility.

This volume consists of 1200 pages of subject matter with over 700 well chosen illustrations. The first 500 pages deal with the anatomy of the female pelvis, physiology, development of the fetus and changes occurring therewith endocrine function and their practical applications in obstetrics, and the conduct of pregnancy and labor. An excellent review of the subject of analgesia and anesthesia is included. The following 700 pages are devoted to the pathology of pregnancy and operative procedures, puerperium. Abnormal pelvis and abnormal pelvis are considered here. The sections on toxemia, extrauterine pregnancy and abnormal pelvis are particularly comprehensive and embody the latest contributions on these subjects. One important omission, however is noted under the Hillis impression method, namely the Hillis impression method. All other methods for attempting to determine the relationship between the size of the fetal head and the maternal pelvis are described. The Hillis impression method since it is the simplest and without the objection of vaginal manipulation, is by far the most practical and useful of all such methods, and should therefore, be included in all obstetrical textbooks.

Stander's third revision of *Williams' Obstetrics* brings it up to date with such recent advances as the importance of the Rh factor in obstetrics and the addition of penicillin and the sulfonamides to the obstetrician's armamentarium but it also retains the simplicity of style and the clear concise presentation of the subject that has characterized this text in previous editions.

CHARLES C. DOWNEY

THE volume entitled *The Osseous System*³ is the fourth of a series of handbooks of roentgen diagnosis being published by the Year Book Publishers. As in previous volumes the material is so arranged that the illustrations and legends on the opposite page and the description and legends on the opposite side. The concise but lucid subject matter is illustrated by 432 figures on 148 plates all in the negative phase. Throughout the text, the author emphasizes the pitfalls of diagnosis and urges that the occasional radiographer always think of the maximum. What might it be besides what I think it is?

The contents of the volume is divided into five sections technique principles of interpretation roentgen anatomy injuries to the skeletal system other than the spine bone diseases occurring abnormalities in childhood bone diseases occurring principally in adult life. A short bibliography appears at the end of each section and an adequate index is appended.

This volume is a handy sized modestly priced atlas and can be recommended to general practitioners surgeons and internists as a diagnostic aid. It should be regarded as indicated as a primer rather than an encyclopedia.

EARL E. BARTT

THE author of *Electrotherapy and Light Therapy*⁴ is an outstanding authority in the field of physical medicine. The fifth edition of this work offers a concise presentation of all present day phases of physical medicine with special emphasis on electrotherapy and light therapy. The newer uses and methods of electronics, electrodiagnosis, ion transfer and ultraviolet radiation have all been incorporated. The chapter on exercise has been considerably enlarged and a new chapter on hypothermy has been added together with a revised glossary covering definitions of electrotherapy and light therapy muscle and nerve action and mechanotherapy. Each chapter has been brought up to date. New illustrations have been added and obsolete ones omitted. The illustrations are excellent.

One of the peculiar features of the book which has enabled it to maintain a position of leadership for fifteen years, is the interesting manner in which the subject is presented. It contains much valuable information, and it is a safe guide to the practitioner's hands of the practitioner.

 HYPERTHERMIA AND MICROANATOMY, BY RICHARD KOWICZ, M.D.
 5th rev. ed. Philadelphia: Lea & Febiger 945

THE subject of this book is physiology not physics from above but physiology from below' not physiology originating essentially to fill human needs and help suffering individuals but physiology as a branch of physical chemical sciences dealing with life as a physical, though exceedingly complex system, that may be subjected to scientific analysis like any other natural object." Quotation is from the preface of *Physical Chemistry of Cells and Tissues* by Rudolf Hoebner et al.

The reviewer is very rough in sympathy with the aims of this book. American science in general, is far too concerned with "practical applications." Nature is a lady who must be wooed for her own worth before she will reveal herself. Certainly there is a tremendous need for such a book as we have here and a still greater need for people with the viewpoint of the authors of this excellent text. It is a book which must be bought by all who wish to understand what is now known about many important phases of life processes.

The first 91 pages were written by David I. Hitchcock and deal essentially with physical chemistry of solutions. He discusses diffusion in solution, reaction velocity thermodynamics, electromotive force, osmotic pressure, electrokinetics and distribution coefficients. Hitchcock stays on broad and well trodden highways. This section is clearly written but parts of it are very scratchy and rather thin. For example, the reviewer doubts that a reader who is not already familiar with thermodynamics could profit very much by reading the chapter on this subject too much territory is covered in the 13 pages. This brevity is carried to extreme in the discussion of dielectric constants, dipole moments and the Debye Hückel theory of strong electrolytes. Two pages are devoted to these subjects!

Section 2 which covers 120 pages was written by J. B. Bateman. In this section Bateman deals with molecular forces, determination of sizes and shapes of large molecules, hydration, protein structure, x-ray diffraction analysis, the structure of crystals and fibers and surface monolayers. There is much excellent material in this section. The part dealing with crystal structure is especially informative. Bateman covers many complex subjects and the reviewer appreciates the great difficulty of presenting these topics simply but it must be said that this section suffers from a lack of clarity.

The strictly biological part of the book begins with Hoebner's section (141 pages) which deals with the penetration of cell membranes by organic non-electrolytes by electrolytes by weak acids and bases by dyestuffs by water and finally he considers the chemistry and physics of plasma membranes. He brings to these subjects more than 40 years of experience and he has performed a great service to all of us by summarizing with completeness and detail the existing knowledge about cell membranes. Hoebner

follows the Collander and Baerlund "lipoid-sieve theory" of cell membranes. He discusses active and passive uptake of substances and describes how they can be distinguished from each other. One cannot help but have the feeling after reading this section that future progress in the study of cell penetration must involve a fuller consideration of the interior of cells. It appears that the penetration and action of narcotics is very obscure and would especially benefit by such expansion.

A section has been contributed by David R. Goddard (71 pages) on the respiration of cells and tissues. Goddard's section is simply written, clear and up-to-date. He deals with the rate of respiration as limited by the rate of diffusion of oxygen. The kinetics of activated reactions are discussed and there is a short chapter on the nature of oxidation, he discusses respiratory enzymes. There follows a chapter on the relation between fermentation and respiration. Finally there is a chapter on the utilization of liberated energy. This last is by necessity very incomplete since our knowledge of this utilization is at the present exceedingly imperfect.

W. O. Fenn has 75 pages on contractile tissues with special reference to striated and smooth muscle. This is a well balanced and critical review of experiments and theories of muscle contraction. It appears from this review that there still remains much to be known about muscle contraction. Muscle physiology has passed through several phases until now it has become a sophisticated science and one has to have a background in several branches of science to appreciate all the modern developments. One can, however, note considerable recent progress and as Fenn writes, "At last the contractile machinery has become more than a structure which is passively acted upon by lactic acid or some other metabolic product. It is as if steam had at last been admitted to the previously empty cylinders of the muscle machine."

Hoebner concludes the book with a section (170 pages) on passive and active transfer in animal and plant tissues. In this section he deals with intestinal absorption, formation of urine, permeability of body surfaces of animals and plants, formation of digestive juices and finally a discussion of some of the mechanisms which may be involved in active transfer. Here again as in the section on cell membranes there is a wealth of detail.

HENRY B. BELL

THE fourth edition of Christopher's *A Textbook of Surgery*, an already well established standard text by eminent American authors, has been made an even more complete and currently correct basic volume for students and reference point for practitioners. This has been accomplished through the addition of sections devoted to recent military experiences as well as the modification of other sections on the basis of progress in both civilian and military surgery. In view of the cautiousness of publi-

cation following the end of World War II remarkably few statements will require considerable correction as a result of reports on military observations made available subsequent to completion of the

present edition. This volume maintains the high standards of format and illustration which characterized previous editions of the work.

AMROSE H. STORCK.

BOOKS RECEIVED

Books received are acknowledged in this department, and such acknowledgment must be regarded as a sufficient return for the courtesy of the sender. Selections will be made for review in the interests of our readers and as space permits.

CLINICAL CONGRESS OF AMERICAN COLLEGE OF SURGEONS

W EDWARD GALLIE, *President*

IRVIN ABELL, *Louisville President-Elect*

Committee on Arrangements

HOWARD PATTERSON *Chairman* FRANK GLENN *Secretary*

PRELIMINARY PROGRAM FOR 1946 CLINICAL CONGRESS NEW YORK, SEPTEMBER 9 TO 13 1946

THE thirty-second Clinical Congress of the American College of Surgeons will be held in New York City at the Waldorf Astoria from September 9 to 13. This will be the first Congress since the 1941 meeting in Boston. Between 1942 and 1945 the Congress was voluntarily cancelled each year in order to lessen the transportation difficulties and to conserve the time of medical and hospital personnel who were overburdened because of the absence of so many of their associates on duty with the armed forces. By autumn the majority of these will have returned and the time seems most auspicious for a great postwar Congress. The preliminary announcement of the plans has been received with enthusiasm by both the military and civilian groups.

CLINICAL PROGRAM

Under the leadership of a strong and representative Committee on Arrangements, plans are under way for a complete and varied program for the five day meeting. The hospitals and medical schools will co-operate in scheduling operative and nonoperative clinics and demonstrations.

COMMITTEE ON ARRANGEMENTS

Howard Patterson,
Chairman
Frank Glenn, *Secretary*
Frank Adair
Albert H. Aldridge
Thomas M. Brennan
E. Jefferson Browder
George F. Cahill
Henry W. Cave
Ralph Cole
Edward J. Donovan
Merrill N. Foot
John H. Garlock

Charles A. Gordon
George J. Hener
J. William Hinton
George H. Humphreys
William F. MacFee
John H. McIlholland
W. Barclay Parsons
Otto Pickhardt
Thomas H. Russell
Raymond P. Sullivan
Howard C. Taylor, J.
William Crawford White
Philip D. Wilson

Visiting surgeons will have ample opportunity to attend well arranged programs of many different kinds in several of the excellent hospitals in the Greater New York area. These programs will include general and special demonstrations such as fractures, cancer, maternal morbidity and end-result studies, clinicopathologic and x-ray conferences, newer diagnostic and therapeutic procedures, preoperative and postoperative supportive treatment, anesthesia and reconditioning. Those interested in operative clinics will have an opportunity to observe newer techniques and surgical procedures. A series of exhibits demonstrating the work of the medical schools and their affiliated hospitals will be available for study in the local hospitals during the meeting, and the basic science departments of the medical schools will present graphic descriptions of their work.

The program of each hospital will be arranged to cover subjects in general surgery, obstetrics and gynecology, fractures, orthopedic surgery, thoracic surgery, neurosurgery, genitourinary surgery, ophthalmology and otolaryngology. A daily clinical bulletin will be published to show the presentation of subjects under these classifications so that the visiting surgeon may select the programs which he wishes to attend.

CONVOCATION AND PRESIDENTIAL MEETING

The opening evening session of the Clinical Congress will be devoted to the combined presidential meeting and convocation. Since the last Congress in 1941 a total of 2,744 surgeons have been received into fellowship *in absentia*, and to them in particular the Convocation on the opening night of the Congress will be a long anticipated event. Many of these new Fellows have been

AMERICAN COLLEGE OF SURGEONS

serving with the armed forces. The formal initiation ceremonies, always impressive, will be exceptionally so this year because of the large number of new Fellows accepted during the past four years who are expected to be present, in addition to the 1946 group of initiates.

Officers, Regents, and Governors have remained in office since 1941 because of the cancellation of annual meetings of the Fellows and Governors. Especial interest will also therefore be attached to the installation of the officers-elect consisting of Dr Irvin Abell of Louisville, chairman of the Board of Regents as president Dr Leland S McKittrick of Boston as first vice president and Dr F Phinizy Calhoun of Atlanta as second vice president.

Dr W Edward Gallie of Toronto who has been president since November 1941 will give the Presidential Address.

SCIENTIFIC SESSIONS

The scientific sessions to be held on Tuesday Wednesday and Thursday evenings, will be addressed by eminent surgeons and specialists, recognized as authorities in their fields. Special scientific meetings will be arranged on the same evenings for specialists in ophthalmology and otolaryngology. The newest developments in general and special fields will be presented in a well rounded program for these evening sessions.

Every afternoon from Monday through Thursday panel discussions led by recognized authorities in each field aided by well qualified collaborators, will be held. Similar meetings held during past Congresses have been most successful largely because of the fact that they permit the participation of a large number of surgeons, thus increasing the opportunities to learn from the experiences of others.

Preliminary plans include the holding of a symposium on fractures and other traumas on one afternoon, and a symposium on cancer on another afternoon. There is always wide interest in these special meetings. Plans for several new features have been discussed but cannot be announced until definite decisions have been made in co-operation with the Committee on Arrangements.

FORUMS ON FUNDAMENTAL SURGICAL PROBLEMS

Great interest has already been shown in the plans for reviving the Forums on Fundamental Surgical Problems which were so popular at the Boston meeting. Research activities have been retarded but not stopped during the war period

and the accumulation of the results of five years of work since the last Congress will certainly assure the presentation of intensely interesting material. The plan is to conduct these forums on Tuesday Wednesday Thursday and Friday mornings, and to include in them brief reports of original clinical and experimental observations relating to the broad aspects of surgery and surgical specialties. No prepared discussions are planned but questions and comments will be invited. The enlistment of the interest of young men who are doing original work, through these forums, is one of the most beneficial results of these sessions which are now considered to be an indispensable feature of every Clinical Congress.

MEDICAL MOTION PICTURES

Medical motion picture exhibits will again be an appreciated feature of the Clinical Congress. The latest available pictures showing surgical procedures and related subjects will be shown. The accumulation of such pictures during the war has not been great but nevertheless a surprising number of new films are being received for review by the College and an interesting variety of educational pictures is assured. The schedule will be arranged so as not to conflict with either the clinical program at the hospitals or the scientific sessions. Both sound and silent standard and color films, will be shown all of which have been approved by the Committee on Medical Motion Pictures.

HOSPITAL CONFERENCES

The first formal session of the Clinical Congress will be the opening meeting of the twenty fifth Hospital Standardization Conference. Dr W Edward Gallie of Toronto president of the College, will preside. The hospital conferences will continue on Monday afternoon, with sessions following on Tuesday Wednesday and Thursday mornings, afternoons, and evenings.

Hospital administrators, members of governing boards, heads of the various hospital departments and their personnel nursing groups and many other persons directly or indirectly concerned about hospital progress will be interested in the discussions of current hospital problems. National organizations representing various groups of hospital personnel will co-operate and participate in the meetings, which will include formal sessions, panel discussions round table conferences, and open forums.

ADVANCE REGISTRATION

The hospitals and medical schools of New York City afford accommodation for a large number of

visiting surgeons, but to insure against over crowding attendance at the Congress will be limited to the number that can be comfortably accommodated at the clinics. The limit of attendance will be based on a survey determining the available facilities in the participating hospitals and schools. It is therefore expected that surgeons who wish to attend the Congress will register in advance.

In accordance with a resolution adopted by the Board of Regents fellows of the College whose dues are paid to December 31, 1946 Initiates of the classes of 1942, 1943, 1944, 1945 and 1946 and fellows in military service will not be required to pay a registration fee for the 1946 Clinical Congress. For endorsed junior candidates the fee is \$5.00. Surgeons, not fellows, who attend as invited guests of the College, will pay a registration fee of \$10.00.

For purposes of identification at the registration desk, fellows should present their fellowship cards. Those surgeons who pay the registration fee in advance will receive a formal receipt which they will exchange for a general admission card upon presentation at the registration desk in the Waldorf Astoria Hotel.

HEADQUARTERS AND TECHNICAL EXHIBITION

Headquarters for the Congress will be established at the Waldorf Astoria where there are excellent facilities. The Technical Exhibition will be held on the Third Floor near the Grand Ballroom. Leading manufacturers of surgical instruments and supplies, sutures, dressings, pharmaceuticals, operating room equipment, x ray apparatus, hospital equipment of all kinds, and publishers of medical books will be represented in the exhibition, which will provide visiting surgeons and hospital people opportunities to inspect carefully the newest and best products of all those industries which are helping to improve the service of hospitals and surgeons.

NEW YORK HOTELS AND THEIR RATES

Besides the Waldorf Astoria, there are a number of first class hotels which are conveniently located. In view of the extreme shortage of hotel rooms which is expected still to prevail next September it is urged that reservations be made as

soon as possible. The hotels which are recommended by the Committee appear in the following list

	Minimum Rate with Bath	Single	Double
Allerton House, 143 East 39th Street.		\$2.75	
Allerton House for Women, 130 East 57th Street.		3.00	
Ambassador, Park Avenue & 51st Street.		8.00	
Astor Broadway & 44th Street		3.50	
Barlison (Women), Lexington Ave. & 63rd Street.		3.50	
Barclay 11 East 48th Street		6.00	
Belmont Plaza, Lexington Ave. & 49th Street		4.00	
Beverly Lexington Ave. & 50th Street		5.00	
Billmore, Madison Ave. & 43rd Street.		5.50	
Bristol, 150 West 48th Street		2.50	
Capitol, 51st Street & 8th Avenue		3.00	
Carlisle, Madison Ave. at 46th Street		6.00	
Chesterfield, 130 West 40th Street		2.50	
Commodore, Lexington Ave. & 42nd Street		3.50	
Concourse Plaza, Grand Concourse & 161st Street		3.50	
Cornish Arms, 31 West 33rd Street.		2.75	
Delmonico, 503 Park Avenue		6.00	
Emex House, 166 Central Park South		6.00	
Fifth Avenue Hotel, 24 Fifth Ave. (6th Street)		4.00	
Governor Clinton, 31st Street & 7th Ave.		3.50	
Henry Hudson, 353 West 57th Street		2.50	
Kenmore Hall, 143 East 3rd Street		2.00	
Lexington, 48th Street & Lexington Ave.		4.00	
Luxor Baths Hotel, 1 West 46th Street		2.25	
McAlpin, Broadway & 34th Street		3.50	
Martinkoff, Broadway at 32nd Street		2.75	
Miklodon House, 22 East 38th Street.		3.50	
New Weston, Madison Ave. & 30th Street		4.00	
New Yorker 34th Street & 8th Avenue		3.25	
Paramount, 46th Street, West of Broad		3.00	
Park Central, 7th Avenue & 35th Street		4.00	
Parkside 8 Gramercy Park South		2.75	
Pennsylvania, 7th Avenue & 33rd Street.		3.25	
Piccadilly 227 West 45th Street		3.00	
Plymouth, 143 West 40th Street.		2.50	
President, 234 West 48th Street		2.50	
Prince George, 14 East 48th Street		2.50	
Roosevelt, Madison Avenue & 45th St.		4.50	
Shelton, 40th Street & Lexington Avenue		3.50	
Taft, 7th Avenue & 50th Street		5.00	
Times Square, 43rd Street & 8th Avenue.		2.25	
Tudor, 304 East 42nd Street		2.50	
Victoria, 7th Ave. & 51st Street		5.00	
Waldorf-Astoria, 50th Street & Park Ave.		7.00	
Warwick, 34th Street at 8th Avenue		3.00	
Wellington, 7th Avenue & 57th Street		3.00	
Woodstock, 127 West 43rd Street		3.00

ABSTRACTS OF CURRENT LITERATURE SURGERY OF THE HEAD AND NECK

EYE

Krans, J., and Briggs, W. A. Intraocular Foreign Bodies. Problems of Localization and Operative Procedure. *Brit J Ophth.*, 1945 29 557

In this article the authors discuss intraocular foreign bodies, the problems of their localization and the operative procedures. They point out that the posterior approach for the extraction of intraocular foreign bodies, except in cases in which the foreign body is situated anterior to the lens, has become more popular since the war principally because new materials of low magnetic properties have been introduced into the manufacture of war instruments and munitions. Moreover metallic alloys of low magnetic properties will also most likely be extended into peacetime industry. They suggest a new method of localization which requires a less complicated and delicate apparatus than that of Sweet, as well as a new method of extraction. The limbal method is simple but it is not suitable for intraocular foreign bodies of low magnetic quality or for nonmagnetic foreign bodies nor does it provide an accurate measurement of the point on the sclera to be incised from a fixed point on the eyeball.

The authors recommend a method which gives the exact position of the foreign body in the eye to be operated on and the exact point to be incised on the sclera (determined by 1 lateral x ray picture and 1 posterior picture). To find the diameter of the posterior picture are taken on the same film eye, 3 lateral exposures are taken on the same film with the eye directed forward, upward, and downward. From the x ray films the following data are obtained: the radius of the eyeball, the distance of the foreign body in front of or behind the equatorial plane, the meridian in which the foreign body lies from the center of the eye and the distance of the foreign body from the center of the eye. The procedure comprises the use of a conjunctival flap, exposure of, and incision into the sclera, surface diathermy with 100 ma for 2 seconds (for coagulation) incision of the choroid and interrupted application of the magnet for about 2 seconds at 2-second intervals for 50 times before discontinuance of the procedure as useless.

A diagram of a pair of forceps for the extraction of intraocular nonmagnetic foreign bodies is presented
JOSHUA ZUCKERMAN M.D.

Von Sallmann, L.: Penetration of Penicillin into the Eye; Further Studies. *Arch Ophth. Chic.*, 1945 34 195.

Previous studies on the penetration of penicillin into the eye after topical and systemic use were carried out with commercial preparations and the concentrations obtained in various parts of the eye were expressed in Oxford units. A comparison of these results and those of the author is not possible since he used relatively crude preparations and titration according to the Oxford method was not done. The Fleming dilution method was used and the concentrations were given in micrograms per cubic centimeter.

Three local methods designed to introduce comparatively high concentrations of the drug in the anterior segment of the eye were tested on rabbits and the results compared. These methods were subconjunctival injection, iontophoresis, and applying cotton packs saturated with a penicillin solution.

A comparison of the results with a solution of commercial sodium penicillin containing 5,000 units per cubic centimeter showed that the highest concentration was obtained in the aqueous by iontophoresis, and in the cornea and the iris with the ciliary body by the prolonged application with cotton packs. The lowest concentration in the aqueous, cornea, and iris with the ciliary body was observed after subconjunctival injection.

Extremely high concentrations were found in the cornea and the iris with the ciliary body after the application with cotton packs saturated with a solution containing 20,000 Oxford units per cubic centimeter. The content in the aqueous was also higher following this method than after any other.

The ocular tissues and aqueous were almost completely free of penicillin 8 hours after iontophoresis with a solution containing 5,000 Oxford units per cubic centimeter and after a solution containing 20,000 Oxford units per cubic centimeter was applied by saturated cotton packs.

I generally traces were found in the lens and iris after typical administration.

Direct illumination on human eyes with normal and with edematous corneas gave more erratic results and much lower values than direct illuminations on rabbit eyes.

LESTER L. MCCOY, MD

Dena F. P.: Tuberculosis of the Choroid with Inclusion of Bone Tissue (Tuberculosis de la corioidea e inclusion de tejido óseo) *Arch. de oftalmología* 1915 3: 207

A child 5 years of age was sent to the author for examination on account of faint vision, photophobia, and redness of the left eye. Direct illumination showed a tumor of the anterior part of the eyeball, involving chiefly the choroid. General examination showed a primary tubercle of the lung, which was active exudative slight in extent but moderately advanced. The Mantoux reaction was positive at 1:1000. Apparently there had been a hematogenous dissemination of tubercle bacilli from the lung to the left eye.

After 6 months of treatment at a tuberculosis hospital the pulmonary condition was greatly improved but an iridocyclitis had developed in the eye and its condition was such that enucleation was considered advisable. The surgical specimen showed a chronic inflammatory process with nodules made up of various types of cells, predominantly epithelioid cells and Kooster's follicles.

There were also fragments of bone in the choroid but there was no apparent reaction around them. There were evidently two independent findings: a primary hematogenous tuberculosis of the choroid and a metaplastic connective tissue in the conjunctival tissue of the choroid. Some of the bone fragments were within the tuberculous tissue and some of them outside of it. It seems probable that the organization of the choroid tissue took place in embryonic life and that the bone tissue created a point of least resistance which favored the localization of the tubercle in there. ARTHUR G. MORRIS, MD

Márquez, M.: The Technique and Clinical Value of Injection of Hypertonic Salt Solution into Tenon's Space in Detachment of the Retina (Técnica y valor clínico de las inyecciones intratentonianas hipertónicas en el desprendimiento de la retina) *Arch. de oftalmología* 1915 3: 207

A case of traumatic detachment of the retina is described in a boy of 13 years who was injured with a shotgun, one of the shots lodging in the external part of the lower conjunctival cul-de-sac and causing great external hemorrhage and pressure on the eyeball. There was detachment of more than half of the lower part of the retina with a small irregular perforation of the macula, through which the red color of the choroid could be seen. Central vision was abolished as well as more than half of the upper and a part of the internal vision.

This case was treated by a preliminary injection of 1 cc of 2 per cent novocain hydrochloride

followed by the injection into Tenon's space of 1 cc of hypertonic salt solution originally 15 per cent but reduced to 12 per cent by the addition of further anesthetic. This proved superior to the 20 and 30 per cent solutions formerly given. Three injections were given. The visual field was restored to about normal and the visual acuity was greatly improved but not restored to normal.

Several other cases presenting successful results are reviewed briefly and a case in which the treatment was not successful, probably because of detachment of the choroid by extensive hemorrhage. Rest in bed and paralysis of the ciliary muscles with atropine are useful supplementary measures.

Detachment without rupture and rupture with detachment are discussed and the importance of studies of the visual field is emphasized. One must state that this method has not been used more extensively because of the fact that injection into Tenon's space has been confused with subconjunctival injections. The subconjunctival space exists only over the superior third of the eyeball and is superficial. However, Tenon's space is deep and surrounds the posterior part of the eyeball. The needle used for the injection is curved with the opening toward the outer side of the needle which is turned to ward the center of the eyeball. The injection is made slowly inferiorly and externally and as far back as Tenon's space as possible.

Many cases are cured by this method, but if it fails it does not interfere with the later use of surgical procedures. ARTHUR G. MORRIS, MD

Klein, B. A.: Syndromes Leading to Enucleation (I) *J. Ophthalmology* 1915 23: 1193

The results of the studies reported in this study show that there are several other equally important or frequent conditions besides chronic suppurative infiltrating iridocyclitis which lead to enucleation or suggestion of sympathetic ophthalmia after trauma.

The eyes selected for this study had in common a chronic low grade painful state of irritation or inflammation. They were classified into 3 groups: (1) those in which the terminal inflammation was continuous with the immediate post-traumatic reaction and (2) those in which a quiescent interval varying from several weeks to years preceded the activated state of inflammation.

Group 1 consisted of (a) chronic mild septic iridocyclitis which was characterized by moderate photophobia, pain and ciliary injection (b) extensive tissue necrosis with marked contraction of the penetrating injury (Clinically the predominant finding was a complete hyphema which remained stationary without any signs of absorption) (c) sympathetic ophthalmia which in half of the cases had no quiescent interval between the injury and the enucleation. Four of the 6 cases showed the fellow eye to be involved at the time of enucleation. These 4 include the 3 eyes with a quiescent interval.

Group 2 consisted of (a) chronic post-traumatic infiltrating iridocyclitis in which the interval be-

SURGERY OF THE HEAD AND NECK

tween the traumatic reaction and the appearance of the corneal precipitates in the injured eye was usually from 8 to 14 days, (b) endogenous iritis. Two of these cases had a tuberculous uveitis which was bilateral. Two other eyes become painful and inflamed suddenly after 7 and 40 years respectively during an attack of influenza, (c) chronic hemophthalmos, illustrated by a case of double perforation of the eye with glass which resulted in profuse intraocular hemorrhage and required enucleation four years later (There was marked photophobia and ciliary injection in the fellow eye), (d) epithelial implants (Secondary glaucoma considered the most frequent complication of epithelial implants was present in only 3 of the 9 cases), (e) rupture of the degenerated lens and (f) extensive retinal dissection and detachment. Six cases showed this condition, in which a mild late iritis required removal.

Seventy seven eyes were enucleated 17 or 22 per cent, presented nonspecific infiltrating iridocyclitis 9 or 26 per cent, chronic septic endophthalmitis 9 or 26 per cent, epithelial implants 8 per cent, chronic hemophthalmos, extensive contusion ne crosis, and late toxic iritis after longstanding retinal detachment 5 per cent, endogenous iridocyclitis 3 per cent some rarer conditions and 8 per cent sympathetic ophthalmia.

EAR

Lindsay J R Oppenheimer M J Wycis, H T., and Spiegel E. A.: Receptor Apparatus of the Vestibulovascular Reaction Arch. Otol. Chlc. 1945 41 257

The labyrinthine reflexes upon the vegetative nervous system form an essential part of the various types of sickness caused by motion. Information is lacking regarding the receptor apparatus for such reflexes and therefore this study was undertaken.

The observation had been made (Spiegel and Scala) that in cats in which for other reasons bilateral puncture of the round windows had been made, rotation failed to produce a fall in the blood pressure but still was able to produce a fall in the blood pressure. Since the otolithic apparatus might still have been the origin of the vasomotor reaction the present experiments were undertaken to determine the effect of labyrinthine stimulation on the blood pressure after the otoliths had been thrown off the maculae, to abolish the tonic labyrinthine reflexes.

Guinea pigs were centrifuged according to the method of Wittmack to dislodge the otoliths. The animals were tested for postrotatory nystagmus, reflexes on linear acceleration and positional reflexes before and after centrifugation. Centrifugation for 1 minute at 1500 revolutions per minute resulted in the obliteration of the positional reflexes (righting of the head and compensatory eye movements) and the partial or complete loss of reflexes on linear acceleration but in most of the animals the postrotatory nystagmus remained undiminished which indicated active responses from the semicircular canals. How

ever a fall in the blood pressure could still be elicited upon rotation. Histological preparations confirmed the dislodgment of the otoliths from the maculae while in most instances the cupolas could be observed in their normal positions.

The experiments show therefore, that the reflexes on the vasomotor system do not depend alone upon a functioning otolithic apparatus. However, they do not rule out the possibility that the otolithic apparatus may contribute to the vasomotor reaction. The vasomotor response had formerly been shown to persist after abolition of the postrotatory response but to disappear temporarily on the injection of cocaine in alcohol to paralyze the whole labyrinth. Several interpretations are possible from these experiments but it seems not improbable that the labyrinth functions as a whole as a receptor for reflexes on the vasomotor system and that the various receptors can substitute for each other.

JOHN R. LINDSAY M.D

Druza J G: Aural Manifestations of Leucemia Arch. Otol. Chlc. 1945 41 267

An analytic review of the medical records of 148 subjects with leukemia admitted to the Mount Sinai Hospital in New York, New York, over a period of 5 years yielded the following conclusions.

Aural complications of leukemia are more prevalent than is generally believed. They occurred in 25 of the 148 cases reviewed or in 16.8 per cent. Routine examination of the ears including functional tests of the cochlear and vestibular nerves would disclose an even greater incidence in all likelihood. The aural complications include diseases of the external middle, and internal ear and of the adjacent structures. The pathological changes in the ear as elsewhere in the body are comprised chiefly of hemorrhage, cellular (leucemic) infiltration, and inflammation. Pathological changes in the ear may be revealed on histological examination even in cases in which there was no clinical evidence of aural disease at any time during the illness.

Otitic infections are comparatively more severe in the leucemic than in the nonleukemic patient. They do not infrequently show a strong tendency to early invasion of the adjacent structures. The diagnosis of acute mastoiditis in a leucemic subject may paradoxically be made more difficult by the presence of postauricular swelling and sagging of the bony external canal wall since these signs so well recognized as pathognomonic of suppuration in the mastoid bone may under such circumstances also represent leucemic infiltration in the adjacent soft parts.

NOAH D. FABRICANT M.D

Lindsay J R: The Significance of a Positional Nystagmus to Otoneurological Diagnosis. Laryngoscope 1945 55 527

Postural vertigo and its accompanying positional nystagmus is the most common type of vestibular disturbance in diseases of the central nervous system. It occurs less frequently in peripheral ear

diseases. The syndrome can be produced during routine positional tests. In the lesion central and peripheral in type of positional nystagmus may be differentiated. The first type which is regular in direction or changes direction with alteration of the position is found only in diseases involving the central vestibular pathways. The second type with constant direction may occur in either central or peripheral diseases. Attack of vertigo of the pseudo-Ménière type in which auditory disturbances and central neurological signs are absent have been found to exhibit a postural character as a predominant feature.

In a series of more than 30 cases of the pseudo-Ménière type with positional nystagmus at the time of examination the first type was found in all but 1. This would appear to be strong evidence of a central location of the disturbance. It is possible in the basis of a societal study to differentiate several groups in the general pseudo-Ménière group such as hypertension and arteriosclerosis, toxic involvement by drugs, infections and hypotension while a small number remain doubtful as to etiology. Approximately one half of these cases could be included in the hypertensive group on the basis of low blood pressure and evidence of vasomotor insufficiency. (Ann. Otol. Rhinol. Laryng. 64: 1945, 333-35)

Weinstein, L., and Acheron, H. B.: The Treatment of Acute Suppurative Otitis Media. *J. Am. M. Ass.* 1945 139 53

The authors' purpose in undertaking this work reported in this article was to determine the effectiveness of penicillin as a cure in the treatment of suppurative otitis media and as a means of preventing complications when given very early in the course of the disease, to determine the effective dose range and the length of time over which treatment had to be continued to ascertain whether or not there is any correlation between the total amount of the antibiotic substance required to produce good results and the type of organism in which it is responsible for the infection and to study by means of x-ray examinations the effect of this type of treatment on involvement of the mastoid.

It appears that penicillin is a very effective agent in the treatment of acute suppurative otitis media of which gram positive cocci are the cause.

Complications of suppurative otitis media are reduced to a minimum and mastoiditis which is by far the most common of the sequelae following middle ear infection is almost completely eliminated by penicillin therapy.

Fifty cases of acute suppurative otitis media 45 of which occurred as a complication of scarlet fever were treated with varying doses of penicillin intramuscularly. The external auditory canal was free from exudate in 82 per cent of the patients in less than 4-5 days following the institution of therapy. Recurrence of the infection was observed in 16 per cent of the patient and these responded well to treatment with larger doses of penicillin.

There appeared to be some degree of correlation between the total dosage of penicillin required to effect a cure and the type of organism producing the middle ear infection. Infections in which the hemolytic staphylococcus aureus was present alone or in combination with the beta-hemolytic streptococcus seemed to be more resistant to therapy but responded to larger quantities of the antibiotic agent.

Complications of acute suppurative otitis media were reduced to a minimum, and mastoidectomy was infrequently necessary.

Secondary infections with gram negative bacteria were controlled by the local administration of 10 per cent urethane and 1 per cent sulfanilamide aqueous solution.

The following regimen is suggested for the treatment of acute suppurative otitis media: intramuscular administration of 55,000 units of penicillin immediately after the appearance of exudate in the external auditory canal and repetition of the same dose every 3 hours until the aural discharge has been completely absent for 72 hours.

H. B. Acheron, M.D.

Atkinson, M.: Ménière's Syndrome; Consideration of Results of Medical and Surgical Treatment. *Arch. Neur. Psychiat. Chic.*, 1945, 54 107

The author reviews the various medical treatments in popular use for Ménière's syndrome including salt-free diet and dehydration, sodium fluoride plus ammonium chloride, low salt diet and ammonium chloride, high potassium diet, histamine intravenously and nicotinic acid. It is believed that each of these methods of treatment will give some temporary relief of vertigo in from 65 to 95 per cent of cases. The incidence of improvement in deafness and in tinnitus varies from 9 to 36 per cent. Speculating on the cause for the similarity of results obtained with these various medical treatments the theory of a common basic factor which is affected favorably by all of these treatments is suggested. Increased capillary permeability is suggested as such a factor and may be due to one of two causes: anoxia from a diminished blood supply or retention of some form of protein or chemical. On the basis of the favorable action of each of these various medical treatments might be explained. The author has had better experience with nicotine acid and histamine desensitization in appropriate cases than with other treatments.

Surgical treatments for the prevention of attacks of vertigo are also discussed.

Reichmann's operation on the sacculus endolymphatic sac does not sacrifice hearing but has not met with general favor probably because of 25 per cent failures. Removal of foci of infection, while recommended highly by our writer, has failed to give results in the hands of others. Sectioning of the vestibular division of the eighth nerve is criticized because of its failure to relieve the deafness and tinnitus although the latter may sometimes be improved. Operations on the labyrinth consist of two

types those which destroy the labyrinthine function completely and those which destroy only a part of the vestibular function. The former has the undesirable result of destroying hearing and is unsuitable in bilateral cases or those with useful hearing in the affected ear. Experience with the second type of operation is not yet sufficient, but it seems to offer a safer and more logical procedure in that hearing is preserved.

In conclusion the author points out that medical treatment will relieve or control attacks of vertigo in about 80 per cent of cases and will give relief from tinnitus in about 50 per cent. Hearing can be improved in about 20 per cent of cases. Surgical treatment is recommended only as a last resource to abolish attacks of vertigo.

JOHN R. LINDSAY M.D.

Fowler E. P. Early Diagnosis and the Arrest of Otosclerosis (Clinical and Histological Otosclerosis) *Arch. Otol.* Chic., 1945 43 353

Otosclerosis is the name given to a disease of bone which begins in the bony wall of the labyrinthine capsule. It can be diagnosed only by the occurrence of deafness which is due to a limitation of mobility at the annular ligament which impedes the vibration of the stapes. Such signs as a pinkish glow from the promontory, an apparent increase of hearing for bone conducted sounds, a positive Gellé test, immovability of the malleus, a normally patent eustachian tube, scantiness of cerumen hairs and sweat glands in the external canal, and a family history of otosclerosis with no previous history of aural disease all point to a diagnosis of otosclerosis, but all of these signs may be absent in the presence of otosclerosis and all may be present in the absence of otosclerosis.

Available statistics based on histopathological examination (Guild) indicate that 7.55 per cent of white people harbor otosclerosis, but that only about 1 per cent have ankylosis of the stapes. Adequate statistics in the colored population are lacking, but those available indicate a much lower incidence of otosclerosis, possibly 1 per cent. The disease tends to be most active under the age of 20 and least active after the age of 60 years.

The only clinical indication of beginning ankylosis of the stapes is a slight lowering of the hearing acuity for the lower frequencies. In uncomplicated active otosclerosis with ankylosis the loss of hearing progresses inversely with the frequency or pitch of the tone. There is as yet no knowledge as to the etiology. A similar disease of bone has not been found in other parts of the skeleton.

In order to detect early otosclerosis every child should be examined when it enters school and a history of progressive deafness in the family should lead the observer to examine the child more frequently and to institute measures to correct any abnormalities. Attention should be paid to hormone factors and certain vitamins and minerals, especially around the age of puberty. There is no impressive evidence

that the fenestration operation arrests the otosclerotic lesion.

JOHN R. LINDSAY M.D.

Shambaugh G. E. Jr. Fenestration Operation: A Clinical Study of the Permanence of Its Results. *O. Bull. Northwest Univ. Med. School* 1945 19 259.

The history of the fenestration operation is the story of the search for a method of making a labyrinthine fistula that would remain open.

The early operations failed because new bone formation always closed the fistula with loss of hearing improvement in a few weeks or months after operation. It is now possible to create a fistula in the bony labyrinth that will usually remain open. This is due to advances and changes in technique during the past few years and the author's technique employed most recently shifts the position of the fenestra and the application of the skin flap so as to enhance the conduction of sound vibration from the tympanic membrane to the fistula. This has been employed in 173 operations.

Closure of the fistula to sound occurred in 6.57 per cent of 800 consecutive fenestration operations. Analysis of these cases showed that with each improvement in technique the percentage of closure diminished. The majority of the closures occurred within the first year after operation and in only 2 cases did they occur later than two years after operation.

The criticism most frequently levelled against the fenestration operation has been that the hearing results would be transitory because of bony closure of the fistula. This prediction was borne out in part in the early operations done by the original Lempert technique. Successive improvements in technique, however, have successively reduced the percentage of failures due to bony closure. With the technique used by the author during the past 2½ years 77 per cent of the cases permanently maintain a functionally wide open labyrinthine fistula with maximum hearing improvement, while 86 per cent present a significant hearing improvement.

JOHN F. DELPEL M.D.

NOSE AND SINUSES

Lumsden R. B. Otolaryngology in the Army. *J. Laryngol.* Lond., 1945 60 91.

The author reviews his experience in otology during a period of 4½ years in the Middle East.

Otitis externa presented a high incidence in the summer months, particularly among new recruits compared to seasoned troops. Swimming appeared to be an etiological factor, but was not of prime importance. Acute otitis media showed a high incidence during the summer which also was related to swimming, only a few of the patients observed had not been swimming shortly before the onset of infection. Swimming while suffering from a cold appeared to be the most important factor in the onset of both otitis media and acute sinusitis.

The results which followed limited local use of penicillin in the treatment of chronic sinusitis were unconvincing. The author's opinion was that the climate was not beneficial to upper respiratory infections.

During the year of 1911 and early in 1912 31 per cent of patients with acute otitis media required no treatment. During the similar period in 1913 and 1914 87 per cent of patients required operation.

A review of the complication of otitis media showed 3 cases of meningitis with 2 recoveries, 3 cases of lateral sinus thrombosis with 2 recoveries, 4 cases of temporosphenoidal lobe abscesses with 3 recoveries, 5 cases of labyrinthitis with 5 recoveries, and 3 cases of multiple complications all fatal. The incidence of petrositis in the complicated cases particularly in patients with labyrinthitis was high. Atrophic rhinitis seemed to be aggravated by the hot dry climate and all but the mildest cases had to be returned to a temperate climate. Diptheria proved to be a more dangerous disease in the Middle East than in temperate climates. Neuritis was a common complication and frequently extensive.

Approximately 20 per cent of casualties of all types were found to have sustained some acute trauma. Mixed deafness was found in 40 per cent of such cases. In one hospital over 40 per cent of ruptured drums in traumatic cases had a suppurated otitis media. This was attributed probably to unwarranted local interference particularly with the syringe and insufflation of sulfonamide powder. The only local procedure which was advised in such cases was the application of a plug of cotton wool and removal of impacted wax with a scoop when necessary.

MOUTH

Eberius, H.: Cancer of the Lip. A Clinical Study of 778 Cases with Particular Regard to Predisposing Factors and Radium Therapy. *Acta Med. Stockh.*, 1943 45 12.

In his investigation of the Radiumhemmet lip cancer material the particular aims of the author have been (1) to find a practical definition of the term, "lip cancer," (2) to throw light on the significance of the so-called predisposing factors and of the precancerous conditions in the development of lip cancer, (3) to clarify the differential clinical pictures of the lip tumor, (4) to determine the frequency of metastasis, the usual time of its appearance and its relation to the status of the primary tumor, (5) to illuminate certain technical problems of treatment in interstitial irradiation, (6) to evaluate the radiological treatment in relation to the cure results obtained on the basis of calculation, i.e., without the elimination of specific categories of cases, and (7) to discover which factors influence the curability of lip cancer and thereby the prognosis.

The author had at his disposal a series of 807 cases of lip cancer from the years 1910 to 1935. All 778

cases of lip cancer which have been accepted for treatment have been followed up to January 1, 1941 when this investigation was terminated.

In the present study the term "lip cancer" is used exclusively with regard to cancer arising in the epithelium of the red of the lip. In all cases of lip cancer in which treatment is at all possible, the local tumor should be treated radiologically. Rather small, not too deeply growing cancers can advantageously be treated with radium. Larger tumors should be treated with roentgen rays. In cases with operable lymph node metastases the main stress should be laid upon the surgical treatment in connection with which both preoperative and postoperative roentgen or teloradium treatment should be given. Inoperable metastases should be treated with roentgen rays or preferably teloradium interstitial irradiation of remnants of metastases can also be used. Prophylactic roentgen treatment of the lymph node regions is recommended for cases without palpable metastases.

NORM D. FAHRENT, M.D.

PHARYNX

Whitefeather, J. E.: Transitional Epithelial Cell Carcinoma of the Nasopharynx. *Am. J. Surg.* 1945 54 357.

Transitional epithelial cell carcinoma of the nasopharynx is not a rare disease. It never develops too late for successful treatment. The disease affects both males and females of all ages and it is exceedingly malignant in children and young adults.

The most common site of the primary lesion is in or near the fossa of Rosenmüller or in the pharyngeal tonsils. One of the earliest symptoms is referable to obstruction of the eustachian tube. Later symptoms are referable to a polypoid obstruction of the nasopharynx. Invasion of the cranial cavity and metastases to the lymph nodes of the neck. Direct metastases are common.

Radiation therapy is the accepted method of treatment and offers the greatest hope at this time whether it be complete arrest or palliation. Patients who are treated before metastases or intracranial extension occurs can expect the best results.

Sixteen cases of transitional epithelial cell carcinoma of the nasopharynx in patients of from 10 to 58 years of age are reported. Metastases were present in all but 2. Six patients are still living. Of these 3 have the disease and 3 are free of it. None of the latter has survived more than 30 months.

JOHN F. DILLER, M.D.

NECK

Meerna, J. H.: Hyperthymic Epithelial Growth Disease. *Am. J. Surg.* 1945 23 179.

Surveying the several phases or types of Graaf disease one may recognize among others, the following:

- 1 Classic Graves disease, with ophthalmopathy, thyrotoxicosis, and goiter
- 2 Graves disease with thyrotoxicosis but no ophthalmopathy
- 3 Hyperophthalmopathic Graves disease with hyperthyroidism, euthyroidism or hypothyroidism in which the ophthalmic phenomena are the most prominent.

The pathogenesis and etiology of the ophthalmopathy has not yet been definitely established. The available evidence indicates that swelling of the orbital contents is a very important, if not the sole, factor concerned in proptosis of the globes. Weakness of the rectus muscles probably also plays a part and the wide separation of the lids, too, may be a factor. The orbital swelling is believed by many to be due to increase in fat. Although the precise cause of the swelling in the ophthalmopathy of Graves disease has not been established with any degree of certainty it is very evident that the anterior lobe of the pituitary gland has some relation to it.

From the point of view of diagnosis, the problem is not one of distinguishing between etiologically distinct types but of deciding in any given case, whether the ophthalmopathy or the thyrotoxicosis constitutes the greater menace to the patient. The manifestations which render the eye condition disquieting are those reflecting swelling and muscle involvement—bulging of the lids, chemosis of the conjunctiva, limitation of the ocular movements, and diplopia. Limitation of upward movement is the most impressive, and probably the most significant, of the muscle phenomena.

A more difficult diagnostic problem is that of recognizing cases in which the eyes are likely to enter the hyperophthalmopathic phase at a later date, with a view to prophylaxis. Males are more prone to develop the hyperophthalmopathic phase than are females. The early occurrence of subjective ophthalmic symptoms should also suggest the possibility of an impending hyperophthalmopathic course. The early occurrence of chemosis and injection of the conjunctiva and of epiphora is also suggestive of the hyperophthalmopathic type, whereas marked lid retraction phenomena with little or none of the phenomena due primarily to swelling favor the classic type.

The treatment of the hyperophthalmopathic type is specific and symptomatic. Thyroidectomy should be avoided in cases in which the development of a hyperophthalmopathic course is considered likely. Enough cases follow this course postoperatively to justify the belief that the removal of the thyroid plays an important part in initiating it.

The administration of thyroid irradiation of the pituitary gland and administration of substances antagonistic to thyrotropin are among the specific measures used in treatment.

Symptomatic treatment consists of adequate protection of the eyes, depleting measures (on the theory that edema of the orbital tissues may play a part) measures aimed at improving the strength of the

extrinsic muscles and surgical procedures from tarsorrhaphy to enucleation. SAMUEL KAHN, M.D.

DAVIS E. D. D., Lederman M., Harnett W. L., Woodman E. M. and Others. Discussion on the Treatment of Carcinoma of the Larynx. *Proc. R. Soc. M. Lond.*, 1945, 38, 353.

DAVIS reviews laryngofissure for early intrinsic carcinoma of the larynx and compares the results with those in cases treated by radium implantation, radiotherapy or radical laryngectomy. The most suitable cases for laryngofissure excision were those in which the growth was limited to the middle or anterior third of the vocal cord. Extension upward to the ventricular band or into the ventricle was no contraindication to excision, but extension to the subglottic area to the posterior commissure or across to the anterior commissure was regarded as a contraindication to this type of operation. The most successful excisions resulting in cures were those done for epidermoid carcinomas of the Grade 1 Broders type. All the operations were done under endotracheal anesthesia with chloroform and ether. The isthmus of the thyroid was usually divided to facilitate tracheotomy, a procedure no longer considered necessary in every case. When tracheotomy was performed the tube was always removed before the patient left the operating room. Extreme care was always taken to insure against the coming of blood into the larynx. Packing of the larynx with gauze or division of the hyoid bone was considered poor surgery. The alae of the thyroid were not removed, but the tissues about them were freed en bloc. In this series there were no deaths. Two of these cases were formerly treated with telradium but showed recurrences and were then treated by laryngofissure, which resulted in 3 year cures.

COLLIDGE recommended routine biopsy because sessile tuberculosis mimics epithelioma of the larynx. Broders classification from the biopsy specimen if indicative of a Group IV carcinoma would suggest radical operation rather than laryngectomy. After radiation therapy, operative technique may become more difficult and tissue devitalization may result in pharyngostasis or necessitate plastic operations. If radiation therapy fails a radical operation should be done rather than laryngofissure. If general physical debility exists, patients are best treated by radiation therapy which should then be regarded as an alternative method. The technique of burying radium needles in the neck should be abandoned in favor of the telradium beam which can be accurately controlled for dosage and causes minimal or no radionecrosis.

LEDERMAN states that radiation therapy in early cases of intrinsic carcinoma of the larynx can offer the patient as much as surgery and with less risk. Statistics were presented which matched Collidge's report of 70 per cent and 60 per cent 10 year survivals after laryngofissure and laryngectomy.

HARNETT reported a series of 123 cases of cancer of the larynx not yet published. The sex ratio was

113 males to 10 females. The average age of the patients was 62 years. There were 57 patients with early cancer of which 15 were treated by radical surgery and 13 were alive after 4 years. Of the 50 in the latter group treated by palliative methods all were dead. Of the 19 treated by radium 8 survived and of the 13 treated by x-ray 4 were alive. The operative mortality from laryngofibrosis (52 cases) was 8.3 per cent.

WOODMAN believes that the method of opening a window into the larynx and inserting radium needles into the lesion should be defended and not be abandoned. He also noted that x-radiation may be given through the window as a follow-up for recurrences.

LISKI states that the preservation of the patient's life rather than his voice should be considered before surgery is recommended. Cerepi can be better controlled now because of new drugs. Hence the result of radiation therapy will become more striking. After laryngofibrosis radiation therapy should be given to decrease the percentage of recurrences.

NAGEL reports that patients treated with x-ray therapy do not completely avoid damage to their voice as is commonly believed. They also suffer from the prolonged treatment and x-ray reaction. Perichondritis is a complication after irradiation. Laryngofibrosis is superior to radiation therapy if the malignancy is of low grade. Patients treated by the

Finis Harmer method of radium implantation through a window in the larynx made uneventful recoveries and suffered little radiation sickness.

WILSON's results from either radiotherapy or surgery did not equal those reported. Wilson thinks that surgery should never be attempted after extensive radiotherapy. He also believes that there is no reliable method of predetermining the radioactivity of a lesion.

BROWN believes that surgery should be limited to simple carcinoma of the cord. The most important advances in laryngeal surgery consisted of the elimination of tracheotomy by means of intubation and the control of bleeding with the cautery point.

CANNITTIN states that tracheotomy is of great value because it diminishes the muscular activity of the pharynx and larynx and thereby promotes better healing.

DAVIS states that the Harmer Finis operation is superior to other forms of therapy because it enables one to give the proper dosage of radium over the area to be treated whereas telerradium and x-ray produces burning of the skin and other complication in the surrounding tissues.

COLLIER and GILL that the local use of radium causes an irregular radiation effect and the tumor properties are not given an homogeneous dose.

REY, M.D. C. P. Saurony, M.D.

SURGERY OF THE NERVOUS SYSTEM

PERIPHERAL NERVES

Sporling R. G.: *Peripheral Nerve Injuries*. J Am Med Ass 1945 129 1011

In the European theater of operations 15 per cent of all battle injuries to the extremities were complicated by nerve damage. If such injuries are mishandled the patient may be left with a useless, anesthetic limb; therefore it was extremely important to set up a program of treatment for them.

Immediate primary suture of a severed nerve is theoretically desirable, but in practice it is not a good plan because battle injuries are almost invariably associated with contusion of the nerve tissue. The optimum time for end-to-end suture is between the third and the ninth weeks after injury.

It was not always possible to return patients with injury of the peripheral nerves to base hospitals for definitive treatment during the optimum period because these injuries were last on the list of priorities for evacuation among neurosurgical cases. These patients usually reached neurosurgical centers in England two to three weeks after wounding. Meanwhile the wounds had been debrided and delayed wound closure done. Most of the definitive treatment was given in England rather than the United States because the optimum time for repair would have passed before the latter could be reached. However, the patients were usually sent to the United States for convalescence. Many serious wound infections or extensive injuries of the soft tissue requiring plastic repair were sent directly to the United States, by-passing England.

Several points were outlined for the management of peripheral nerve injuries in the Manual of Therapy for the European theater.

1. In every wound of the extremities, damage to the nerve trunks must be considered and motor and sensory tests should be made.

2. Even in the presence of nerve injury the wound should be treated as any other soft tissue wound that is, by debridement and delayed closure.

3. If severed nerve ends are visualized during the debridement, they should be approximated if possible. If the gap is too great to permit this both ends should be anchored to the soft tissue with fine steel or tantalum wire. This is to prevent retraction which sometimes complicates later end-to-end suture. Metal sutures aid in later visualization by means of x rays.

4. Muscles and fascia should be approximated loosely over the exposed nerve trunk. No pack should be used. The wound should be closed later.

5. For transportation splints should be applied whether there is associated bone injury or not.

6. The condition of the nerves at operation and the procedure done should be noted on the emergency medical tag or on the cast.

The following principles of nerve repair were stressed.

Nerve ends should be trimmed until normal tubules are visible. The ends should be approximated by epineural sutures with no tension on the suture line.

Hemostasis must be rigid. The use of a through and through suture (sliding stitch) was optional. The recommended suture material was fine tantalum wire on an atraumatic needle.

A small cuff of tantalum foil was usually placed over the suture line, although at one installation a plasma clot (Tarlov's technique) was used.

Removable splints were used rather than casts for the correction of deformities due to injuries. Extension of the flexed joint was begun at the end of the second week after operation and was completed by the fifth week.

Physiotherapy was applied both before and after operation. Galvanic stimulation of denervated muscles will prevent atrophy and retard fibrosis and, accordingly this measure was used routinely, beginning with 15 brisk contractions daily and progressing to 30 contractions. Massage active and passive motion, and moist and dry heat were also used.

There were 6,245 battle casualties with major nerve injuries hospitalized between D-day and V E day. Of these 46 per cent were operated on overseas. The remainder were evacuated to the United States for definitive surgery usually because the neurosurgical centers abroad were overloaded.

In 47 per cent of the surgical cases the nerve was found intact and neurolysis usually external was done. In the remaining cases the operation consisted of end-to-end suture. The number of insurmountable nerve gaps amounted to 1 per cent, as opposed to the 10 per cent found among the cases in which operation was performed in the United States following the North African campaign. This is important because elective bone shortening to facilitate end-to-end suture is not desirable and most nerve grafts are clinical failures.

Early nerve suture possesses three advantages over delayed suture: (1) mobilization of the proximal and distal nerve segments is more readily achieved; (2) fibrosis in the wound, particularly in the nerve stumps, is minimized; and (3) flexion of the contiguous joints is more easily accomplished.

The time lapse between wounding and neurosurgery varied from 28 days in the period after D-day to 42 days in the period of heavy fighting before V E day. The average for the whole period was 39 days which was longer than the optimum period but well within the upper limit of 90 days.

Primary wound healing occurred in 98 per cent of the cases, and demonstrated the wisdom of delaying neurosurgery for three or four weeks.

results he devised a surgical technique which was subsequently modified by Freeman and Watts in 1942. The latter believe that the correct procedure is the division of the anterior thalamocortical fibers, hoping thereby to disassociate the emotional and intellectual components of morbid thought processes.

The authors then review a series of cases 100 in number and divided into 49 male and 51 female patients whose average age was 36 (their ages ranging from 19 to 53 years). This material included 4 cases of melancholia, 5 of severe obsessional states, 2 epileptics subject to frequent attacks with impulsive outbursts and a general parietic, who having had treatment, developed a chronic hallucinosis. The remaining 88 patients were suffering from schizophrenia, 54 of them being catatonics mostly of the excited hyperkinetic type and 13 schizophrenics of the hebephrenic type who were sullen and withdrawn from reality although with occasional impetuous and violent behavior. Judged by ordinary prognostic standards all of these patients were considered hopeless chronic invalids.

The operative technique as described by Freeman and Watts was used throughout the series. From a technique standpoint the operation was a straightforward procedure with few complications, the mortality in the series being 4 per cent. The importance of expert postoperative management is stressed. The impression of the authors that the best results are achieved in cases showing signs of "mental tension" is supported by this series. In the schizophrenia group periodic catatonics gave the best results. It is concluded that the value of the operation in certain types of emotional illness has been well established.

PAUL MERRILL, M.D.

Frykholm, R.: The Treatment of Bilateral Acoustic Tumors. *Acta chir scand* 1945 91: 451.

The incidence of bilateral acoustic tumors has been a subject of discussion for many years. In 1915 Henschen regarded the ratio of bilateral to unilateral acoustic tumors as being 1 in 10. Cushing in 1917 believed that many cases of unilateral tumors were not reported and that probably the ratio was closer to 1 in 100. In the clinic of Professor Olivecrona, in Stockholm during the period from 1922 to 1943, there were recorded 241 cases of unilateral and 6 cases of bilateral acoustic tumors.

The author discusses the cases of 54 patients with unilateral tumors, who were operated upon in this clinic during the period from 1937 to 1939. Radical enucleation of the tumor with preservation of the facial nerve was the objective, for in intracapsular enucleation the nerve is nearly always spared.

Radical removal of the tumor with preservation of the facial nerve was done in 27 cases with 3 deaths, radical removal without preservation of the facial nerve was done in 14 cases with 3 deaths and intracapsular enucleation was done in 13 cases with 2 deaths.

This vast experience was available in the treatment of 6 patients with bilateral tumor, 3 of whom

had a generalized neurofibromatosis. The cases are carefully recorded and it is apparent that they presented many surgical difficulties for 3 of the patients died within 2 months after operation. Frequently operation in two stages was necessary despite the bilateral approach and in no case was a radical removal accomplished on both sides with preservation of function in the facial nerves. The most satisfactory result was obtained in the second case already reported in which the patient is alive 17 years after bilateral intracapsular enucleation. In 3 cases, the tumor on one side was radically removed the tumor on the other side was not dealt with. Thirteen cases in which surgical treatment was carried out have been collected from the literature.

The syndrome presented in bilateral acoustic tumors is as would be expected except that the condition does not necessarily progress evenly on the two sides. There is tinnitus, nerve deafness, loss of nerve conductivity, absence or diminution of corneal reflexes, and roentgen evidence of dilatation of the internal acoustic meatus. These are followed by cerebellar signs, such as ataxia and nystagmus and finally there is increased intracranial pressure with vomiting and papilledema.

In the surgical treatment of acoustic tumors certain aims and restrictions must be observed.

There should be a bilateral approach and the dura should not be closed unless both tumors are removed with their capsules. Complete enucleation should be attempted only on a deaf ear. Radical removal should not be undertaken if one facial nerve has already been paralyzed. If the patient is completely deaf, both tumors should be radically removed provided the facial nerve on the first side functions; a two-stage operation may be indicated.

Alpers, B. J. and Forster, F. M.: Arteriovenous Aneurysm of the Great Cerebral Vein and Arteries of the Circle of Willis. Formation by Junction of the Great Cerebral Vein and the Straight Sinus and of the Choroidal Arteries and Anomalous Branches of the Posterior Cerebral Arteries. *Arch. Neur. Psychiat., Chic.* 1945 54: 181.

The authors report a case of arteriovenous aneurysm involving the great cerebral vein (Galen) and the arteries of the circle of Willis. This patient was an 18 year old male with a history of headaches for 18 years. His neurological study was essentially negative but x rays revealed a calcification in the right parieto occipital region, convolutional indentations of the inner table of the skull and complete destruction of the dorsum sellae and the posterior clinoid processes.

Ventriculograms revealed an internal hydrocephalus with a calcified mass projecting into the posterior horn of the right lateral ventricle.

Cranotomy was performed and the ventricle opened which revealed a mass of tortuous arteries

SURGERY OF THE NERVOUS SYSTEM

roots are cut bilaterally from T_{12} or T_{11} to S_1 . Any local tendon shortening which remains can be cared for by manipulation or tenotomy. With splints the flaccid legs can be stabilized to bear weight and with the addition of crutches the patients can learn to walk. Because the bladder no longer empties except when it reaches its critical amount of filling or when deliberately stimulated the patients can remain dry.

In the first of such operations attempted success was not complete because of difficulty in identifying the proper anterior roots, which were counted from what was thought to be S_1 upward. The patients expired from sepsis arising from the urinary tract or bed sores. This has been eliminated in recent years by the use of tidal drainage with solutions M or G as irrigating fluid which also does away with bladder calculi that otherwise occasionally form.

In dorsolumbar anterior rhizotomy the spinous process of T_{12} is identified. A bilateral laminectomy of T_{11} and T_{12} is done. After the dura is opened, the last teeth of the dentate ligament are identified, since the intraspinal nerve which encloses it and leaves by the next dural opening below is the first lumbar. All anterior roots from T_{11} to S_1 are then sectioned but none below S_1 should even be cut. If the patient is very deformed the laminectomy can be done in the lumbar puncture position. Pentothal sodium or an avertin base is the preferred anesthetic.

Since the operation is permanently destructive it should be limited to those patients who have anatomical cord transection. The requirements for this diagnosis are complete absence of voluntary motor power, complete sensory loss, a predominantly flexor

or flexor adductor contraction in the abdominal muscles and in both legs in response to a noxious stimulus applied to the sole of either foot, and the emptying of the bladder in accompaniment to this stimulus or other less noxious stimuli. Although the presence of an extensor thrust had been thought in the past to predicate neural cord connections above and below the lesions, the author has found that its presence or absence is not necessarily an indication of anatomic cord transection and consequently it has no bearing on whether or not a given patient needs an anterior rhizotomy. Of primary importance is the elimination of infection and the establishment of a good general condition since the lack of a good general condition distorts the neurological status.

Ten such rhizotomies have now been performed by the author with the conversion of spastic paraplegia to the flaccid type in all cases. Twenty-four hour urinary control without catheter or drainage has been attained in all but 2 cases. Bed sores and pressure sores were healed or arrested in all cases before operation. Two patients have developed bowel control so that defecation occurs only once a day at a predetermined hour. Three others are well on their way to attaining this end. In the others sufficient time has not yet elapsed. All but 2 are either walking with splints and crutches or learning to do so.

Other patients have not been operated on because of the inability to control sepsis or hypoproteinemia, or because of inadequate intelligence on the part of the patient or ability to get along fairly well in spite of spasticity.

ROBERT E. GREEN, M.D.

and veins in the region of the glomus. More of the ventricle was incised which exposed a mass of vascular abnormalities lying against the tentorium with the vascular stem of attachment toward the midline.

The patient succumbed 2 days following operation, and necropsy studies were done. These revealed an extensive aneurysm arising from the junction of the great cerebral vein (Galeu) with the straight sinus, and with rather extensive arterial communications. The arterial supplies could be followed into it from both choroidal arteries and direct communication could be traced from these arteries to the posterior cerebral artery on each side. A branch from each posterior cerebral artery could be followed while coursing around the mesencephalon and sending branches into the aneurysm.

Only 2 cases of a similar type of arteriovenous aneurysm have previously been reported and both of these were associated with an internal hydrocephalus, the mechanism of which has not been adequately explained. HOWARD A. BROWN, M.D.

Gantt, W. H., and Marshall, E. K., Jr.: Toxicity of Sulfanilamide on Higher Nervous Activity. *Bull. Johns Hopkins Hosp.* 945 77-104.

The authors found that the oral administration of large doses of sulfanilamide considerably exceeding the therapeutic dose produced a generally depressing action upon the conditional reflexes in dogs. Two dogs with previously well established salivary conditional reflexes and a dog with cerebellar motor conditional reflexes became ataxic when given 0.5 gm. of sulfanilamide per kilogram of body weight. The diminished conditional reflexes returned to normal the day following the experiment and there was no permanent impairment of cortical function. GEORGE FRANK, M.D.

Spiegel, I. J., and Lewin, P.: Tourniquet Paralysis. *J. Am. M. Ass.* 1945 139 432.

The authors believe that paralysis of a peripheral nerve follows the application of a tourniquet for hemostatic purposes more often than would be suggested by review of the literature. The reason for this is that most of the lesions produced by the tourniquet are only transitory.

Three cases of peripheral nerve paralysis presumed to be due to application of a tourniquet are described in detail furthermore in each case the particular nerve involved was surgically explored and visualized. Neuromas were found on the nerve in 2 cases with thinning of the nerve structure below the lesion and in the third case the nerve was found to be embedded in scar tissue. The lesion was so extensive in all of the cases that end-to-end suture could not be accomplished because of the long length of nerve that would have to be sacrificed and it then seemed that the peripheral nerve injury would be permanent. Pathological investigation of the nerve lesion was not feasible for none of the nerve was removed. The time of operation was relatively uncertain but in 2

cases the tourniquet was supposed to have been applied for approximately 1½ hours and in the third case for approximately 35 minutes.

In spite of these lesions the tourniquet is to be considered a very important adjunct in surgical procedure on tendons, nerves, bones and joints.

Munro, D.: The Rehabilitation of Patients Totally Paralyzed Below the Waist, with Special Reference to Making Them Ambulatory and Capable of Earning Their Living. *B. Exptl. Med.* 1945 233 453.

With proper treatment all patients with injury to the spinal cord who are intelligent, co-operative, and have the use of their shoulders, arms, and hands can be made to live a socially useful existence.

Among a series of 243 patients with thoracic, lumbar or sacral cord disease observed at the Boston City Hospital 59 cases were analyzed. They were chosen according to the following criteria: the patient must have lived 90 days after the onset of the disease; he must have been rendered incapable of doing gainful work; and the lesion must have been below the second thoracic level. The present study is concerned only with complete anatomic transection of the cord.

Following recovery from spinal shock, patients with anatomic transection develop a "maximal flexor response to a minimal known stimulus," provided the state of nutrition is good and no major infection is present. This reflex consists of dorsiflexion of the great toe, flexion of the ankle, knee and adduction and flexion of the hip. The flexor and extensor tendon reflexes are both hyperactive; the flexor muscles are hypertonic while the extensors have normal tone. In addition there is contraction of the abdominal muscles, which stimulates the urinary bladder and causes it to empty regardless of the amount it contains. The more leaves the bladder so rapidly that even if an indwelling catheter is in place it escapes around it. Thus, the patients cannot be kept dry as long as the mass reflex remains active and since they are constantly wet, bed sores remain a problem. The bowels also empty at unpredictable intervals so that the patient is always soiled with feces.

However, if the mass reflex and its effects can be counteracted, the patient can be made ambulatory with splints. The bladder and bowels can also be brought under sufficient control so that the patient can be trained to get through the night without getting wet and through the day without getting soiled or having to empty his bladder more than once every three hours.

The mass reflex is best eliminated by the intraspinal division of the anterior spinal roots. This attacks the logical point, the motor side of the reflex arc, and converts the hypertonic spastic paraplegia into a flaccid paraplegia. It also prevents spread of the reflex activity to the abdominal muscles and the bladder and thus controls the latter. All anterior

roots are cut bilaterally from T_{12} or T_{11} to S_1 . Any local tendon shortening which remains can be cured for by manipulation or tenotomy. With splints the flaccid legs can be stabilized to bear weight and with the addition of crutches the patients can learn to walk. Because the bladder no longer empties except when it reaches its critical amount of filling or when deliberately stimulated the patients can remain dry.

In the first of such operations attempted success was not complete because of difficulty in identifying the proper anterior roots which were counted from what was thought to be S_1 upward. The patients expired from sepsis arising from the urinary tract or bed sores. SURGERY OF THE THORAX

CHEST WALL AND BREAST

Daland, E. M.: Some Unusual Aspects of Cancer of the Breast. *N. England J. M.* 1945 233 515

From previously collected data the author found that there is a much greater life expectancy in patients with carcinoma of the breast who are operated upon than in those who go untreated. A radical mastectomy is considered much superior to a simple mastectomy. Simple mastectomy is reserved as a palliative measure, but x-ray therapy is considered better than simple mastectomy. X-ray therapy is not tolerated well by elderly patients and this group is treated by simple amputation of the breast if a radical operation is considered too formidable.

Three cases of carcinoma of the breast in patients under 19 years of age are reported, also a recurrence 34 years after radical mastectomy and 2 cases of persistent recurrence of low grade cancer over periods of 14 and 10 years respectively.

EARL O. LATIMER, M.D.

Röden, S.: On Cancer of the Breast, with Special Reference to the Results of Different Methods of Treatment. *Acta radiol. Stockh.* 1944 57 5

The author has exhaustively studied 343 cases of carcinoma of the breast treated between 1911 and 1933. The patients operated upon in 1918 and later have generally been subjected to annual examinations. The material was classified according to Stenlind's group I (SI) small and slowly growing larger tumors not fixed to the surroundings and without microscopic metastases to the axilla, group 2 (SII) tumors with axillary metastases as disclosed by microscopic examination, their size being too limited to be classified in Group 3, group 3 (SIII) large and rapidly growing tumors fixed to the skin and underlying tissue with axillary metastases, also all tumors with metastases in the fossa supraclavicularis and further away. There was a total of 343 cases (SI 145, SII 154, and SIII 44).

Operative treatment was given according to Halsted's technique. Electrosurgery was used in 10 cases only. There was a primary mortality of 5.6 per cent.

X-ray therapy has changed throughout the years and on the whole the dosage has been increased. As a rule, therapy can be confined to two fields. The radiation is arranged tangentially to the wall of the breast to lessen the risk of radiation lesions of the lungs. The treatment includes one preoperative and three postoperative series.

There were 127 patients treated by operation alone, 98 by operation and postoperative roentgen treatment, and 118 had roentgen treatment before and after radical surgery.

Of 59 patients in group SI treated by surgery alone 78 per cent survived 5 years and 55 per cent

survived 10 years. After 10 years death due to other causes was as frequent as death due to cancer. Of 17 patients in group SIII treated by operation alone, all died within 3 years.

Of 38 patients in group SI given postoperative irradiation, 71 per cent survived 5 years and 47.9 per cent survived 10 years. Of 51 in group SII, 15.5 per cent survived 5 years, and 13.3 per cent survived 10 years, and of the 9 in group SIII none survived more than 3 years.

The patients treated by irradiation preoperatively and postoperatively included 48 in group SI, 51 in group SII, and 18 in group SIII. Of the first group 90 per cent survived 5 years and 76.3 per cent survived 7 years, but the figures for 10 years are incomplete. Of those in group SII 36.5 per cent survived 5 years and 27.8 per cent survived 7 years. Of those in group SIII none survived for 5 years. The author reports in all cases whether the patient died of cancer or from other causes.

The location of the tumor in the breast is related to its degree of malignancy as follows: (1) upper lateral quadrant, 51 (34.6%) cases less malignant and 96 (65.4%) more malignant; (2) upper medial quadrant, 35 (33.8%) cases less, and 30 (46.2%) cases more malignant; (3) lower lateral quadrant, 18 (40.8%) cases less and 26 (59.2%) more malignant; and (4) lower medial quadrant, 9 (41.7%) cases less, and 10 (58.3%) more malignant.

Data were available in 139 cases of recurrence: 66 cases had recurrence or regional metastases and 73 cases had distant metastases. The recurrences and regional metastases made their appearance on an average of 16 months after operation, while the distant metastases appeared in an average of 21 months. The patients in the group SI developed recurrences or metastases later than those in group SII as would be expected.

EARL O. LATIMER, M.D.

TRACHEA, LUNGS, AND PLEURA

Conant, J. S., and Dale, G.: Closed Extrapleural Pneumonolysis. *J. Thorac. Surg.* 1945 14 34

Closed intrapleural pneumonolysis established itself as a safe and technically satisfactory procedure. Aside from hemorrhagic effusion and subcutaneous emphysema, the complications vary little from those occurring during the course of pneumothorax therapy in patients without adhesions. The procedure has a very low mortality. There is less information, however, regarding the technical results and complications of extrapleural dissection of short pulmonary attachments and those to which portions of the lung are adherent over a relatively wide area.

The author's report is based on 50 operations in which some degree of extrapleural dissection was performed. They represent all instances in which

SURGERY OF THE THORAX

this procedure was used in 143 consecutive intra pleural pneumonolyses. The attachments in these 50 cases were unsuitable for division by the accepted criteria for intrapleural pneumonolysis and under ordinary circumstances these cases would not have been explored. It was possible to obtain satisfactory collapse in 35 or 70 per cent of them by extrapleural dissection. An extensive or complete separation was achieved in 37 cases. If the number performed for exploratory purposes (13) is omitted the operation succeeded in 31 of 37 cases or in 84 per cent of the cases in which an extensive or complete dissection was possible.

No postoperative fluid was noted in 26 cases. Transient effusion occurred in 15 instances. Twenty operations were followed by temperatures of over 100.4 F which lasted no more than 1 week except in the instances in which bloody effusion and staphylococcus empyema occurred. The latter was probably the result of damage to the lung parenchyma in the extremely firm short band. Closed drainage was necessary.

Considerable postoperative bleeding followed the operation in 3 of the patients who had partial dissection (33 per cent) and in 3 patients in the other section (8 per cent). These percentages suggest the various natures of the attachments. The patients with attachments which after exploration are found to be too dangerous to dissect also appear to be the ones associated with the greater percentage of postoperative hemorrhagic effusion, even though the operation is not persisted in. When extensive or complete dissection is possible postoperative oozing is rather infrequent. Dense attachments are frequently vascular and it is suggested that the normal respiratory tug at the denuded line of attachment when exaggerated by coughing and occasional vomiting has the opportunity of rupturing vessels and loosening the coagulum following cantenization of the bleeding points.

There were 6 cases of empyema 5 of which were tuberculous. All of them developed 4 or more months after the procedure. One case of staphylococcus aureus empyema occurred postoperatively.

As to the technique a new type of sponge carrier and dissector previously described by the authors was used in 45 of the 50 operations. The Coryllos pneumonolysis unit was used in nearly all of the cases.

JOSEPH K. NARAY M.D.
Brantigan O. G.: Resection of the Lung in the Treatment of Pulmonary Tuberculosis. Arch Surg 1945 51: 147

Tuberculosis is a systemic infectious disease caused by a specific micro-organism. It most often involves the lung and is usually bilateral, but unfortunately the major disease area is predominantly unilateral and often nilobar. The application of adequate medical measures supplemented by simple surgical procedures will arrest or cure early pulmonary tuberculosis in most cases. Often in the later stages of the disease irreversible structural

changes occur in the bronchial system and cause the failure of ample therapeutic measures.

Accurate diagnosis is extremely important in recognizing irreversible structural changes in the lungs and bronchial system. The use of tomography, bronchography, determinations of intracavitary pressure, bronchoscopy, bronchospirometry and diagnostic pneumothorax as indicated will lead to the correct diagnosis of pulmonary lesions. Only with an accurate diagnosis can the outcome of surgical treatment be predicted.

Pulmonary resection is the only form of treatment that can be used effectively when pneumothorax or phrenic paralysis with or without pneumoperitoneum does not control basilar disease a cavity against the mediastinal surface in the lower half of the chest, or a cavity in the middle portion of a lung. The isolated tuberculous represents a localized form of pulmonary tuberculosis and it is perhaps the only condition in which all of the diseased tissue can be excised.

Controversy is invited when lobectomy is suggested for the treatment of a tension cavity and of unilateral or unilobar disease in a young person. Real contention and perhaps just criticism are encountered when lobectomy of the upper lobe is elected as the method of treatment instead of thoracoplasty.

The criticism of elective lobectomy of the upper lobe for tuberculous must not be allowed to react generally against pulmonary resection for tuberculous. Good results in the whole field of medical and surgical practice depend primarily on the treatment instituted early in the course of any disease.

Nine cases are reported in which resection of the lung was indicated for the treatment of pulmonary tuberculosis. One case resulted in death. This patient had been subjected to a bilateral pneumothorax and a thoracoplasty in a period of 8 years, before undergoing lobectomy performed a year after the final stage of the thoracoplasty was done. If the failure of the thoracoplasty could have been predicted after the failure of the pneumothorax, pneumectomy could have been performed as a primary type of treatment. In 1 of the cases in which removal of a tuberculous was indicated excellent postoperative recovery occurred. The remaining 7 cases showed that the patients were definitely benefited even though the disease was not cured in every case. In 5 of the 9 cases reported, the patients had endobronchial disease. When tuberculous disease of the bronchial stump occurs, there is always the danger of the formation of fistulas months or years after the operation. Endobronchial disease often responds to the bronchoscopic application of silver nitrate even when an infected lung is distal.

Dissection of the hilar structures, which permits individual ligation of the pulmonary artery and veins and also adequate suture of the bronchus with silk, has greatly reduced the development of bronchial fistulas. The dissection in persons with tuberculous has been uniformly easier than dissection in persons with other pulmonary conditions which re-

quire lobectomy or pneumonectomy. Unfortunately tuberculous disease often is located in the upper portion of the lower lobe which places it at the region of the incomplete fissure. As every effort must be made to avoid cutting into tuberculous tissue, the resection, therefore, must frequently be carried into the remaining healthy lobe. Technically it is often less difficult to do a pneumonectomy.

No drainage is used in cases of pneumonectomy and lobectomy of the upper lobe, since there is no method of immediately obliterating the pleural space. Two grams of sulfanilamide and from 150 to 200 c.c. of chlorazodin (1 to 3,300) in sodium tetradecyl sulfate (1 to 500) are placed in the pleural cavity for bactericidal effect. The same drugs and solutions are placed in the pleural cavity when a lobectomy of the lower lobe is done even though it is drained. If the remaining lobe are freed completely from the parietal pleura the pleural space can be obliterated quickly by the use of a low negative pressure suction apparatus. Obliteration of the pleural space usually will prevent both pyogenic and tuberculous infections. It also offers some assurance against opening of the bronchial stump.

Ether or gas or oxygen and ether (given intra-tracheally) is preferred for the anesthesia. One must try to prevent the aspiration of secretions into the other parts of the lung. After operation the patients are given carbon dioxide inhalations and encouraged to cough and move frequently in order to forestall pulmonary complications. The patients receive 500 c.c. of whole citrated blood 24 hours before operation and from 500 to 1,000 c.c. of blood during the operation. They are placed in an oxygen tent 24 hours postoperatively.

The necessity or desirability of thoracoplasty following pulmonary resection must be considered seriously. Overdistention of the remaining pulmonary tissue might encourage activation of a lesion in a remaining diseased lobe, whereas with thoracoplasty it is well known that collapse of the apical region brings about relaxation throughout the whole chest and favors continued healing of any remaining diseased area. On the other hand, it should be clearly recognized that the best results from lobectomy in tuberculosis will come from treatment of early or minimal lesions. LEX FULLEW, M.D.

Smyth, C. J., and Billingsale, T. H.: The Treatment of Lung Abscesses with Penicillin. *J. Am. M. Ass.* 945, 129, 005

Cases of lung abscesses treated with penicillin previously reported are reviewed and 4 new cases which the authors observed during the past 20 months, are reported.

Thirty-one cases of lung abscesses treated with penicillin had been found in the literature, of which 13 were cured, 8 improved and 10 showed no improvement. A table summarizing these cases and including most of the pertinent data presented in the original report is given.

The 4 patients with lung abscesses who were observed by the authors made satisfactory recovery following the long continued intramuscular administration of penicillin. A summary of these 4 cases is given.

From the authors' experiences and the reports of others, it seems probable that many acute lung abscesses may be cured by this means. In the chronic cases of lung abscesses in which there is adequate drainage through a bronchus, it would appear that recovery may be expected with the use of penicillin alone if it is administered a sufficient length of time. In the cases of chronic lung abscesses which do not communicate with a bronchus to allow free drainage, surgical intervention will probably be required. The authors predict that if lung abscesses are recognized early and treated vigorously with penicillin it can reasonably be expected that the mortality and morbidity from this disease will further decrease.

EUGEN C. ROSENBERG, M.D.

Poppe, J. K.: Limitations of Penicillin in Empyema. *J. Am. M. Ass.* 945, 129, 435.

Penicillin has undoubtedly value in preventing empyema when it is administered in large quantities during the incipient stages before frank pus has formed. This is true especially of postpneumonic pleural effusions of the pneumococcal type. Penicillin is also of value in cases of potential contamination of the pleural space following surgical pulmonary resection and traumatic injuries of the lung.

The period of greatest value, however, appears to be during the incipient stages of the infection, preferably even before a pleural effusion has developed. It is also valuable during the developmental stages of a pleural effusion when the fluid remains thin and clear with relatively few pus cells and a sterile culture. The formation of fluid and positive cultures should decrease rapidly within a few days if the penicillin treatment is to be successful in preventing an empyema. The best results seem to be obtained by a combination of parenteral and intrapleural administration of the penicillin, with emphasis placed on the parenteral route. Intrapleural administration alone has not proved adequate. The use of penicillin to avoid drainage of a collection of thick intrapleural pus appears to represent poor judgment and undue optimism. Admittedly the pus can be rendered permanently sterile in a certain number of cases with tremendous doses of penicillin carried out over a long period of time at great expense to the patient for both the penicillin and hospitalization. The most discouraging part of such treatment is the tendency toward an unsatisfactory result, even after the time, effort, and money have been expended.

A trial of 2 or 3 weeks with daily penicillin dosage of over 100,000 units plus intrapleural injections of penicillin in the presence of a pleural effusion seems sufficient in most of these cases of potential empyema. By the end of this time either the infection should be completely cured or the empyema drained if signs

and symptoms of intrapleural infection persist. More than a week of hospitalization will still be required after the penicillin has been stopped in order to watch for latent empyema of which the symptoms have been masked by the penicillin action. Fifty three per cent of Poppe's cases represent recurrences which developed 1 or 2 weeks after the penicillin was stopped.

Asterile, dry nontoxic empyema cavity following the administration of large quantities of penicillin over long periods of time represents one of the most difficult problems. It simulates the unexpandable lung familiar to those dealing with tuberculous pleural effusions associated with artificial pneumothorax.

The author's experience with penicillin in over 150 carefully evaluated cases of pulmonary infections of all types including empyemas, lung abscesses, and bronchiectasis has shown that penicillin does not alter the surgical principles of treatment in any way. Pus must be drained after it is definitely established and chronically diseased tissue which is irreversibly damaged and replaced by scar tissue must be excised.

Patients who have been cured of their empyema by penicillin should be carefully observed for at least a two weeks period for a possible recurrence. Any toxic or nontoxic turbid pleural effusion containing polymorphonuclear cells following a pyogenic infection treated with penicillin should be surgically drained even though the pus is sterile on culture.

STEPHEN A. ZIEGLER, M.D.

Ovst, G. Indications for Surgery in Penetrating Chest Wounds. *Brit. M. J.* 1945 5: 531

The most important object in the treatment of injuries involving the pleura is early pulmonary re-expansion. By this means pleural infection will be limited and respiratory efficiency restored. The evidence, however, suggests that the prognosis of penetrating wounds is influenced as much by the condition of the lung as by that of the pleura.

Expansion of the lung is slower after penetrating wounds than after nonpenetrating wounds, irrespective of the presence of infection. In both hemothorax and hemopneumothorax, pulmonary re-expansion is less rapid after penetrating wounds. In total cases of pneumothorax the prognosis is good in the case of nonpenetrating injuries but after penetrating wounds the chances of persistent pulmonary collapse are high even in the absence of infection. This is the type of case which most frequently calls for surgical evacuation of the pleural hematoma. In most cases this difference is due to pulmonary injury which is not always recognized and treatment directed to the pleura alone will not always result in re-expansion of the lung. Difficulty in resolution of the hemopneumothorax nearly always means pulmonary injury with bronchopleural fistula.

The prognosis of penetrating wounds, moreover, is worse than that of nonpenetrating injuries because pulmonary re-expansion is slower and pleural infection is more likely. Elimination of the pleural space

is of such significance that it is reasonable to regard early pulmonary re-expansion as even more important than avoidance of infection. The former is a more useful means of promoting the latter and the prognosis of localized basal empyema is much better than that of persistent total hemopneumothorax even if the latter remains sterile.

Pulmonary contusion and laceration on the other hand are important causes of delayed expansion of the lung and are nearly always found in the condition of unresolved hemothorax.

Penetrating wounds of the upper lobe have the worst prognosis and are nearly always present with total or apical unresolved hemothorax. If this persists for more than two weeks surgical evacuation is indicated in all cases except those of basal hemothorax.

The main principles of treatment of penetrating wounds therefore are early elimination of pneumothorax and hemothorax and early surgical débridement of large wounds of the lung and pleura.

HEART AND PERICARDIUM

Trent J. C.: Surgical Therapy on the Patent Ductus Arteriosus. Report of 5 Cases. *Arch. Surg.* 1945 51: 106.

A patent ductus arteriosus is a constant threat to life if allowed to persist. The early diagnosis of uncomplicated patent ductus arteriosus is important, therefore, and can be made in almost 100 per cent of the cases if the following criteria are present: (1) a machinery murmur, (2) thrill in the pulmonary area, (3) enlarged pulmonary artery, (4) enlarged heart, (5) enlarged pulmonary vessels, (6) abnormally increased pulse pressure, (7) stunting of growth, (8) normal sense of cyanosis and clubbing of fingers, (9) normal electrocardiogram, and (10) a history of heart disease from early childhood. Not all these criteria may be present in every case.

The presence of a machinery murmur is listed by most observers as essential for the diagnosis. Although in rare instances the diagnosis may be made without it, such diagnoses remain open to question until proved by autopsy or operation.

Surgical therapy is not applicable in all cases of patent ductus arteriosus. As a rule only in those cases in which the patent ductus is uncomplicated by other serious developmental defects is ligation suitable.

All methods employed to date, short of complete division of the ductus, are attended by a certain number of recurrences. Simple ligation with silk wrapping the ligated duct with cellophane in the hope that the fibrosis thus promoted may cause permanent obliteration of the lumen ligation and division of the ductus, each has its good points and hazards.

Ligation of the duct with cellophane offers the safest and most efficient method of occlusion. Hence prophylactic ligation of the uncomplicated patent

ductus arteriosus by qualified surgeons offers the possibility of a normal life expectancy to many patients who otherwise have little hope of living beyond the age of forty STEPHEN A. ZIMMAN M.D.

ESOPHAGUS AND MEDIASTINUM

McHenry L. C.: Benign Esophageal Strictures. *J Oklahoma M Ass* 945 38 469

Benign esophageal strictures are caused primarily by cicatricial contracture of the esophageal wall as a result of injury and healing processes. These injuries are caused most frequently by corrosive chemicals, at times by foreign bodies, by instrumental trauma, by ulceration from severe infections such as typhoid fever and by peptic ulcer. Household lye, which is composed of 95 per cent sodium hydroxide, is by far the most common causative agent. Small children attempt to drink such solution or find the dry powder and mistake it for sugar. Adults at times ingest these caustic substances by mistaking them for some medicament and at times attempt suicide by purposeful ingestion. First aid measures such as dilute vinegar or lemon juice with large amounts of water must be administered very quickly to limit appreciably the extent of the injury. By the time the doctor sees the patient the damage has already been done. Immediate treatment can then be only palliative and supportive. Under proper care the patient may get along fairly well for from two weeks to two months when swallowing becomes more difficult or even impossible because of secondary closure of the esophageal lumen. The ulcerations may be healing and the closure be caused by fibrosis and contracture. Secondary infection may have caused increased swelling, granulations, and even further extension of the tissue damage. This will of course, eventually result in more extensive fibrosis as healing occurs.

Treatment must be directed first toward preserving the life of the patient, second toward maintaining his general state of health so that he may heal his lesions, third toward maintaining a patent esophageal lumen and last toward restoring this lumen to a size compatible with relatively normal esophageal function.

If the patient is in shock he must be treated generally for shock as in any serious injury. Parenteral fluids are usually necessary to maintain fluid balance and prevent acidosis. If there is definite laryngeal obstruction tracheotomy may be necessary. The use of gentle mechanical suction to remove profuse secretions from the mouth and throat is very helpful. Keeping the mouth clean not only makes the patient more comfortable but helps prevent stagnation of infected mouth secretions. Measures such as penicillin and the sulfonamides to prevent secondary infection are of definite value. If the patient does not begin to swallow liquids within a very few days the performance of a gastrostomy will make possible the maintenance of nutrition.

If the patient can be persuaded to swallow a thread and to let the thread remain in place he will

never develop complete occlusion of his esophagus. Attempts to keep the esophageal lumen open by the use of catheters, Levine tubes, or bougies during the stage of acute ulceration are at times successful, but they are dangerous and add an element of trauma to the pathology already present.

Estimation of the degree of damage to the esophagus and of the extent of healing is made by x-ray study and by esophagoscopy. The latter must be done very cautiously and usually only the most proximal portion of the involved area can be visualized.

Once the ulcerations are healed or nearly healed, the problem of obtaining and maintaining an adequate esophageal lumen must be considered.

Dilatation of the strictured esophagus is obtained by passing bougies through the esophagus in gradually increasing sizes. Eventually almost all can be restored to practical function. Except for very mild injuries a lumen of normal size and flexibility is rarely attained. There are several methods of dilatation commonly used. The most easily used is simple peroral passage of bougies made for use in the esophagus. It is rightly called "blind bougienage" in that the operator cannot see that the bougie is engaged in the lumen of the stricture. There is usually a dilated area above the stricture and this is often sacculated with the small lumen lying on the side wall of the sacculatation. A blindly inserted bougie is apt to impinge on the thin wall of the sacculatation rather than enter the lumen and if an appreciable amount of force is used perforation will result. This method is the least effective and the most dangerous of any under consideration. Peroral passage of bougies through an esophagoscope is used in clinics where facilities and trained personnel are available to perform frequent esophagoscopy. A method used almost entirely in several excellent clinics is the passage of bougies over a string which the patient has swallowed. If sufficient string is swallowed to pass well into the small intestine it may be drawn sufficiently taut so that a bougie passed downward over it will be certain to engage in the lumen of whatever passage is present through the esophagus. The fourth method of dilatation was devised by Gabriel Tucker and is known as retrograde bougienage. It necessitates a large gastrostomy. The patient wears the string continually one end being brought out through the abdominal wall, the other through the nose and the ends tied together.

The authors advocate early gastrostomy when the patient cannot or will not swallow a thread. It allows early feeding of a seriously injured patient and the maintenance of a favorable state of nutrition. Freeing the injured esophagus from the irritation of the necessary passage of food allows earlier healing of the local lesions. Lastly, it enables the surgeon to use the most effective and least dangerous of the methods of dilatation.

The authors have studied the records of 53 patients who have suffered burns of the esophagus.

There were no patients under 1 year of age. Over one-half of the patients were 3 years of age or younger. Gastrostomies were performed upon 38 and 21 were treated by direct bouginage only. Usually the bougie was passed through a laryngoscope or esophagoscope with visualization of the proximal stricture. Frequently, after initial visualization of the stricture, simple blind bouginage was employed. Seventeen patients were treated by retrograde dilatations only. Eleven patients were treated by both methods. Three of the series had no dilatations. Many of the patients are treated over long periods of time, the average for the series being just over forty months. The longest period of treatment was eleven years. Eleven patients, just over 21 per cent of the series, died from various causes while under observation. Eight patients, 15.3 per cent, died of perforation of the esophagus by bougies. Four of these were perforated on the first attempt to get a bougie through their esophagus. The authors believe that at least a portion of this mortality might have been prevented if early gastrostomies had been done and no attempt made to dilate the esophagus until healing of the ulcerations had taken place.

Approximately 75 per cent of the patients are eventually relieved of their obstructive symptoms. They lead normal lives and except that they must be very careful to masticate their food thoroughly get along very well.

Abbott, O. A. Abnormal Esophageal Communications. Their Types, Diagnosis and Therapy.
J. Thorac. Surg. 1945 14 382

Abnormal acquired fistulous communications may occur from the esophagus into the bronchial tree, pleural cavity, mediastinum, pericardium, and more remote tissue spaces. The etiology of such conditions depends upon the same factors which may cause fistulas elsewhere, namely malignant tumors, inflammatory diseases, trauma, and possibly predisposing congenital abnormalities. Carcinoma of the esophagus and bronchial tree, and malignancies of neighboring structures constitute the most frequent mediastinal fistula formation. A fistula may develop in conjunction with an esophageal diverticulum. Such a diverticulum is most likely to be of the traction or acquired type so that the diverticulum itself plays a secondary rôle in the actual etiology. The types of trauma which are found reported include gunshot wounds to the chest, penetration by sharp objects, crushing injury to the chest, penetration by bone fragments and surgical procedures such as bougie dilatation, esophagoscopy and anastomoses.

An esophageal fistula presents a serious hazard to the patient's life but not necessarily a hopeless one. The author's report adds 6 permanent closures to the 15 previously recorded. Two unusual cases of esophageal pericardial fistulas are included in the reports. Another case in which a fistula between the esophagus and the trachea occurred in association with

Hodgkin's disease is described and in this the communication was successfully treated.

The history of choking paroxysms on the ingestion of fluids is the most dramatic and suggestive diagnostic symptom especially when it occurs in relation to fluids rather than solids. The latter may easily slip past a relatively small aperture. Dysphagia is a frequent precursor of the complication. The patient may describe the ability to swallow fluids without discomfort when in certain positions. The diagnostic measure of greatest value consists of x-ray visualization of the fistula, preferably with iodized oil to prevent barium irritation of the lung parenchyma. Considerable difficulty may be encountered in trying to visualize these communications directly with the aid of the esophagoscope but the instillation of methylene blue within the esophageal lumen followed by bronchoscopic examination can be a helpful measure. In cases wherein the fistula empties into the pleural cavity or through this route to the body surface, one should look for the presence of food particles, yeast cells or the appearance of ingested dyes.

The fundamentals of therapy are first, the maintenance of nutrition and, second, appropriate drainage of the fistula. Many fistulas will disappear spontaneously under this management provided the etiology is non-cancerous. Specific local therapy may consist of topical applications or a direct surgical approach. The question of when to resort to usual nasal tube feedings and when to resort to gastrostomy may be a vital one. It would appear that in all instances if a nasal tube nutrition is indicated in all instances if a nasal tube can be passed. From the frequency with which coughing paroxysms may be initiated on each gavage can be passed. From the frequency with which coughing paroxysms may be initiated on each gavage suggested as a preferable procedure in some cases. This is more mandatory when the lesion is low in the esophagus or at an esophagogastric anastomosis.

In view of the successful result noted and 4 others mentioned in the literature, topical application of a strong cauterizing agent should be given a trial in esophagobronchial fistulas not secondary to malignancy. Should all other measures fail and surgery appear to be indicated, then jejunostomy should be instituted along with satisfactory thoracic drainage at the time of repair. In lesions secondary to tuberculosis the outlook is extremely poor. In view of the secondary invading organisms, open drainage appears mandatory and this should be done anteriorly to allow subsequent thoracoplasty measures as a means of fistula closure. Furthermore, in consequence of the chronicity of these lesions, gastrostomy or jejunostomy should be an early consideration.

JOSEPH K. NARAT, M.D.

Boros, E.: Carcinoma of the Esophagus. A Survey of 332 Cases. *Gastroenterology* 1945 5 106

Carcinoma of the esophagus is one of the most common of all malignant diseases. The tumor is invariably primary and is most frequently found in the male perhaps because of the greater use of

alcohol and tobacco. It is a disease of middle age although cases of persons aged 19 as well as 90 have been reported.

Analysis of the types of cells constituting the tumor showed them to be squamous carcinomas (78%) adenocarcinomas, and undifferentiated carcinomas. On gross examination the tumor can be differentiated into scirrhous, medullary and papillary types.

Unfortunately subjective as well as physical evidence of the presence of an esophageal tumor does not become manifest early. The symptoms are obscure until considerable growth has occurred and loss of weight and strength are little manifestations. Obstructive features often bring to light the nature of the silent process. Glands in the neck may be the first signs, and esophagoscopy should be performed when a doubt exists, but unfortunately the results of the examination are not always satisfactory.

The most prominent symptoms in the order of frequency are dysphagia, pain, weight loss, vomiting, hoarseness, bleeding and coughing.

While the outlook for the patient with esophageal carcinoma is practically hopeless, impetus in the direction of surgical management has been forthcoming. Boros summarizes the operative treatment of 7 patients on whom a total extirpation was attempted. The lesions, however, were found to be inoperable. Gastrostomy was performed on another group of 168 patients, whose subjective complaints such as swallowing were relieved, but no prolongation of life was obtained. The mortality was 25 per cent, and it was questionable how much real benefit was obtained from the operation.

Dilatation of the narrowed esophageal lumen has given satisfaction, and its mortality is low. Dilatation with the Plummer dilator accomplishes the desired end of enabling the patient to eat and carries little attendant risk.

Among the 80 patients subjected to intensive radiation therapy in this series only occasional improvement in deglutition was observed. The improvement, however, was not sufficient to warrant the inference that such could be expected with any measure of certainty as a consequence of the treatment. For the most part there was but little gross change, and the tumor mass showed no signs of shrinkage when compared with the esophagoscopy observations made before treatment. On the contrary, congestion and edema became more pronounced. The length of life of the patient after radiation therapy ranged from 1 to 11 months.

In spite of everything so far devised, carcinoma of the esophagus is practically always fatal and the results of surgery have been almost uniformly bad.

STEPHEN A. ZIEGLER, M.D.

Norris, T. St. M.: Through-and-Through Bullet Wounds of the Mediastinum with Recovery. *Lancet* Lond., 1945 249: 464.

Three cases of through and through bullet wounds of the mediastinum are presented from a series of 11

penetrating wounds of the chest. One of the 11 patients died, but not a case of hemothorax became infected. It is interesting to note that all of the cases except 1 were seen within a few hours of injury.

Case 1 presented a through-and-through bullet wound of the chest. Serum was given by intravenous drip. On the seventh day a roentgenogram of the chest showed a right hemothorax and a hemopericardium. Aspiration of the pericardium was performed and only a small quantity of partially clotted blood was obtained. The patient was out of bed on the twelfth day. He was evacuated on the twenty-fifth day. Three weeks after the injury a roentgenogram showed the heart shadow to be normal and the lung fields clear.

Case 2 presented a through-and-through bullet wound of the chest. The patient's general condition was grave. A blood transfusion was given. Examination revealed a right hemothorax. A needle was passed into the right chest on the eleventh day and 30 ounces of sterile fluid blood were aspirated. Fifteen ounces of sterile fluid were aspirated on the fourteenth day. The patient was evacuated on the seventeenth day. Two months after injury it was reported that the patient's right lung had expanded fully.

In case 3 the patient had been wounded 7 days previously. He had hemoptysis and had been given sulfonamides by mouth. He had a through-and-through bullet wound of the chest. There was a large right hemothorax which was aspirated. The cultures were sterile. He was evacuated 16 days following injury and 9 days after admission to the hospital.

These cases were treated conservatively. When intrathoracic hemorrhage occurred the patients were not operated on for at least a week. The patients were not moved during the first 48 hours, being left in bed in the clothes in which they arrived. They were given sufficient morphine to make them comfortable during this period. Fluids were given liberally by mouth. Penicillin was given intramuscularly, 30,000 units every three hours. When operation of a hemothorax was carried out, 40,000 units of penicillin in 20 c.c. of saline solution were injected into the pleural cavity. Only small amounts of intravenous therapy were given.

RICHARD J. BENNETT, J. M.D.

Humphreys, G. H., and Southworth, H.: Aplastic Anemia Terminated by Removal of a Mediastinal Tumor. *Am. J. Med. Sci.*, 1945 150: 501.

With the exception of tumors of aberrant parathyroid tissue and those arising from the thymus there are no known mediastinal tumors which have general effects. Only a few tumors apparently associated with anemia, because they influence either the formation or the destruction of blood, have been reported.

The 58 year old patient in the case reported by the authors had a mediastinal tumor which had been present for a number of years. It had resisted radio-

SURGERY OF THE THORAX

therapy but showed no signs of malignancy. During a considerable period of observation the patient suffered from a profound depression of erythrocyte formation, although leucocytes of bone marrow origin were never deficient in number. The red cells present were never abnormal in size or shape and there was no evidence at any time of chronic blood loss or abnormal erythrocyte destruction. During this period of anemia, reticulocytes were never found on any attempt except twice when isolated ones were seen within 48 hours of large transfusions. All of the usual therapeutic measures to stimulate red cell formation were without effect. The patient was maintained with transfusions of whole blood and saline suspensions of erythrocytes for 22 months. The mediastinal tumor was removed without difficulty and the patient made an uncomplicated recovery.

Following removal of the tumor a sharp reticulocytosis occurred with a resultant restoration of the erythrocyte count to normal, where it remained for a year after operation. During this period the patient acted on one occasion as a donor for a transfusion, following which her reticulocytes responded normally, and her blood count was not conspicuously affected. Ten months after operation she developed an abscess in the thigh which required drainage and healed slowly. A year after operation the patient rather suddenly developed acute ascites and jaundice went into coma and died. Autopsy showed widespread hemochromatosis and no evidence of reappearance of the original tumor. The nature of this tumor remains in doubt, although a thymic origin was suggested.

MISCELLANEOUS

Ammon, P. C., Burbank, B., Brewer L. A. III and Burford T. H.: Immediate Care of the Wound of Thorax. *J. Am. M. Ass.* 1945 139 606.

A national plan has been adopted for the early preoperative care of the severe thoracic casualty which program is applicable to the thoracic injuries and wounds which may be encountered in civil and industrial practice.

Adequate resuscitation is a necessary preparation for surgery or for transportation. Unless hemorrhage or the urgency of other wounds dictates early surgical intervention the majority of serious thoracic casualties will be greatly benefited if they are not rushed to the operating tables, because patients with extensive contusions of the lungs or heart are poor risks and surgery in these patients should be delayed whenever possible.

The methods of resuscitation are: (1) restoration of normal thoracic physiological conditions including the control of pain and the treatment of hemorrhathorax, anoxia, and pressure pneumothorax; (2) fluid replacement and (3) the early prevention of infection. Oxygen should be freely used before cyanosis develops in any patient who is restless or dyspneic

or whose pulse remains elevated. Caution should be observed in the administration of morphine. Improving thoracic dysfunction consists of nerve block for the control of pain, thoracentesis and water trap catheter drainage for intrapleural pathological changes, and mechanical suction (catheter aspiration bronchoscopy) for the removal of excessive bronchial fluids.

EMIL C. ROBERTS, M.D.

Berk, M.: Cardioesophageal Relaxation. *Gastroenterology* 1945 5 290

Cardioesophageal relaxation or incompetency of the cardiac sphincter is an abnormality in which contents from the stomach regurgitate freely and passively into the esophagus and may be looked upon as a direct antithesis of achalasia (cardiospasm). Although it can be recognized by means of x rays, and though in itself is apparently not a clinical entity, it nevertheless assumes importance in its differentiation from other conditions occurring in the terminal esophagus. It frequently gives rise to symptomatology distressing enough to require medical attention.

In patients observed by Robins and Jankelson the lower 1 to 3 inches of the esophagus was found to be dilated. These authors classified the dilatation into the two types tubular and globular according to the degree of reflux, its duration and possibly on the gastric tone or intragastric pressure. They divided their cases into three groups according to the importance of the condition: (1) those with demonstrable gross pathological changes within the gastrointestinal tract, (2) those with pathological changes outside of the gastrointestinal tract, and (3) those with only functional disturbances. The third group was termed pure cases of cardioesophageal relaxation. All of the patients were considered unstable and being classed as psychoneurotic. In general this group was characterized by hypochlorhydria, and the x rays revealed hypertonicity of the stomach with moderate pylorospasm. No reverse peristalsis was seen.

Two theories as to the explanation of the phenomenon of cardioesophageal relaxation may explain the reflux of barium into the esophagus. First there is an increase in intragastric pressure due to hypertonicity or hyperperistalsis with equal pressure on both openings. The weaker or cardiac sphincter will give way with reflux of the gastric contents into the esophagus. When the tension is relieved the liquid reflux will return to the stomach aided by esophageal peristalsis and its own weight. The second theory has to do with a disturbance in balance of the autonomic nervous system.

The author reports the case of a 47 year old male who gave a history of stomach trouble since 1917 and complained of epigastric distress. The patient's complaints consisted of intermittent episodes of fullness after meals, belching, pyrosis, nausea, regurgitation and rare vomiting. He complained of no true abdominal pain. Relief from his symptoms would come principally from belching, regurgitation of

small amounts of liquid food, and the use of alkali seltzer. Most important of all, he found that when he took the upright position and walked around he would nearly always obtain relief. In addition he began to note during the past few years that when he ate solid foods he would frequently have the sensation that they had been obstructed at the region of the lower sternum.

Cholecystograms, gastrointestinal series and fluoroscopic observations revealed no gross pathology to be present. Films taken in the recumbent position presented a globular mass of barium just above the cardia in the region of the lower esophagus. In the supine and Trendelenburg positions a portion of the barium was seen to roll back into the esophagus and extend as high as the upper third of the latter. In addition, barium was observed to pass to and fro within the esophagus, according to the phase of respiration. When the patient was placed upright the meal was seen to flow back into the stomach.

An esophagoscopic examination revealed that the esophagus was dilated and flabby. Without meeting the least resistance the instrument could be propelled forward into the stomach. There was no true hiatal hernia.

A diagnosis of cardioesophageal relaxation was made. An attempt was therefore carried out to stimulate the smooth muscle tone by the use of physostigmine and prostigmine given both orally and parenterally, without any apparent benefit. Additional drugs which proved ineffective, were dilute hydrochloric antacids and belladonna. The regimen which seemed most beneficial was to have the patient eat a light meal several hours before bedtime and remain erect during that time.

The importance of cardioesophageal relaxation is its possible confusion with other more significant lesions occurring about the terminal esophagus. In fluoroscopic examination, particularly in the erect position, the esophagus appears normal in all respects, except possibly for the normal lack of delay at the epicardia. If fluoroscopic examination is negative in the erect position and a globular or tubular shadow of barium is seen just above the stomach on the immediate films in the supine position, cardioesophageal relaxation should be suspected.

LLE PULLER, M.D.

Paine, J. R., and Plankers, A. G. A Review of Patients with Intrathoracic Disease and Injury Treated on the Surgical Service of a United States Army General Hospital in North Africa. *Surgery* 1943, 18, 401.

Of 81 patients admitted to the Chest Division of the Surgical Service of a United States Army General Hospital during the period of its operation in North Africa during the spring, summer, and fall of 1943, 66 were battle casualties. The hospital installations were in Nissen huts and tents. Until the end of the Tunisian Campaign this hospital was the most forward of any of the American general hospitals in North Africa. Even at the busiest periods

however the hospital was not called upon to perform primary surgical treatment to any battle casualty except in a few isolated instances.

The report concerns only those patients with intrathoracic disease or injuries involving the thoracic cavity and there was only 1 death during operation, that of a patient with mediastinal teratoma. The treatment of patients with intrapleural accumulations of blood or bloody fluid was accomplished by repeated thoracentesis. Seventeen patients had been subjected to primary major surgical procedures at more forward hospitals, only 1, however, was treated at this hospital. Twenty-six patients had metallic foreign bodies retained within the chest, but none was operated upon at the hospital. Twenty-five per cent of all patients with intrathoracic wounds or injuries were returned to duty after their stay at the hospital, and one patient with an organized intrapleural hematoma was successfully operated upon with gratifying immediate results.

STEPHEN A. ZIEGLER, M.D.

Harrington, S. W.: The Surgical Treatment of the More Common Type of Diaphragmatic Hernia. *Ann. Surg.* 1945, 22, 546.

In the author's experience with 424 cases of diaphragmatic hernia the most common types which require surgical treatment, in order of frequency are esophageal hiatus hernia, hernia due to trauma, indirect or direct, or to inflammatory necrosis, absence of a portion of the diaphragm, *latus pleuroperitonealis* hernia, and hernia through the foramen of Morgagni.

Each of these various types of diaphragmatic hernia presents different clinical manifestations and requires different methods of surgical treatment. Some of the more important clinical and surgical aspects of these different types are considered in the original article.

The clinical syndrome of diaphragmatic hernia may be divided into two main types. The first occurs in cases in which the stomach is the only abdominal organ involved in the hernia. The symptoms are those of intermittent and usually progressive incarceration and obstruction of the stomach. The most common type of diaphragmatic hernia in which the stomach is the only abdominal viscera involved is through the esophageal hiatus. However, this type of hernia may contain various portions of the omentum, according to the amount of stomach involved in the hernia. Inasmuch as this type is progressive the entire stomach may become involved in the hernia, and the colon may also become incorporated in the hernial sac because of its attachment to the greater curvature of the stomach. More rarely the spleen may become involved because of its attachment to the cardia of the stomach. In the cases in which the colon is involved, there may be additional symptoms of partial or complete intestinal obstruction.

The second type is found in the cases in which multiple abdominal viscera are involved in the

SURGERY OF THE THORAX

hernia. The hernia is usually of traumatic origin and is caused by laceration of a normal diaphragm. However it also may be of congenital origin and may result from congenital structural deficiency of the diaphragm. The symptoms are more varied and severe than those in the first type because of the multiple structures involved and they are often more acute in onset. The initial symptoms may be those of acute intestinal or gastric obstruction or severe hemorrhage.

In the treatment of all hernias that have occurred through the left portion of the diaphragm, the author prefers the abdominal approach by means of an oblique left rectus incision starting at the ensiform cartilage and extending to the outer border of the rectus muscle. He believes there is less risk of thoracic complications when this approach is used. It is of particular advantage in cases of esophageal hernia for the herniated stomach is usually confined in a sac in the posterior part of the mediastinum and does not enter the true pleural cavity.

In the repair of hernias through the right portion of the diaphragm the author prefers the thoracic approach because the large, right lobe of the liver makes the abnormal opening in the diaphragm inaccessible from the abdominal approach.

The technical difficulties of adequate exposure of the hernial openings through the left portion of the

diaphragm and the esophageal hiatus are often considerable because of fixation of the left lobe of the liver to the leaf of the diaphragm. The exposure is greatly facilitated by cutting the suspensory ligament and retracting the left lobe of the liver to the right. This can be accomplished when the left lobe is small, by folding it on itself, and when it is large by retracting it forward into the wound. The spleen is often very adherent to the posterior part of the diaphragm and hernial openings, but usually can be separated from these structures by blunt dissection. In some instances the spleen has been so traumatized by the injury and so bound into its abnormal position by adhesions that it cannot be separated from the hernial opening without seriously injuring it. This not uncommonly occurs in the traumatic types of hernia, and occasionally in esophageal hiatus hernia. In cases of this type splenectomy is necessary.

Paralysis of the diaphragm produced by temporary or permanent interruption of the phrenic nerve, is of value as a procedure preliminary to radical operative repair of esophageal hiatus hernias. It is a necessary procedure in the surgical treatment of partial thoracic stomach resulting from a congenitally short esophagus. In some cases in which radical operative repair is contraindicated it may be used as a palliative measure.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Gatch W. D., and Montgomery W. F.: External Hernias Containing Gangrenous Bowel. *J Am Med Ass* 945:290-736.

A review of the reports on strangulated hernia published since 1913 shows that the results of treating this condition are as poor now as they were then. In fact the death rate is about as high today as it was in the days of preaseptic surgery. The plan of treatment described by the authors briefly consists of three parts:

1. Incision of the hernial sac together with the gangrenous bowel within it.

2. Deflation of the obstructed bowel with a Miller Abbott tube down to the point where it is obstructed at the hernial ring. This restores it to a healthy condition and permits giving the patient liquids and soft foods by mouth, which corrects starvation and dehydration.

3. Laparotomy done after the tube has been down for about a week (through a low paramedian incision): excision of the gangrenous bowel, and intestinal anastomosis; plugging of the femoral ring with omentum stitched to it and treatment of the abdominal wound with sulfathiazole after closure of the peritoneum.

Three case histories are given.

EMIL C. ROSENBERG, M.D.

AIRD I: Acute Nonspecific Mesenteric Lymphadenitis. *Brit Med J* 945: 680

Although often described in British, American and other medical literature the author believes that acute nonspecific mesenteric lymphadenitis has found no general acceptance as one of the commonest causes of acute abdominal pain in children and as an occasional puzzling affection of adults. As a rule the term is omitted from the index and text not only of surgical manuals but even of encyclopedic reference works, and there are hospitals in which all inflammatory enlargements of abdominal lymphatic glands are presumed to be tuberculous. If the condition is mistaken for acute appendicitis as it frequently is, no great harm is done. It may be wise to sacrifice accuracy for safety. Material injustice may be caused however if the disease is wrongly labelled "tuberculosis" the patient's medical record is distorted, relatives are subjected to unnecessary anxiety and the premium for a life insurance policy may be raised.

As to the pathological features, the mesenteric glands—juxtaintestinal along the mesenteric attachment of the lowest few feet of ileum, intermediate along the ileal arteries and terminal on the main superior mesenteric trunk—are discretely enlarged. The first or the last of these groups may be involved alone or all three groups may suffer together. The

anterior and posterior cecal and ileocolic glands or may not be simultaneously affected. The intestinal glands are predominantly involved in early stages of the disease, early in an attack they may be pink in color but usually they are found to be white. The intermediate and terminal glands are predominantly affected in later stages of the disease, they seem always to be white in color. The mesenteric glands are soft and juicy at first, elastic later, and finally quite hard. It is uncertain whether obstruction ever occurs in nontuberculous adenitis. The leaves of the mesentery, and if the terminal superior mesenteric glands are involved the adjacent peritoneum of the posterior abdominal wall, are congested. The peritoneum of the anterior abdominal wall is nearly always unaltered. The ileum, at times the cecum and appendix as well, may show serious hyperemia, and sometimes a patchy edema of the whole thickness of the bowel wall. This inflammatory appearance of the intestine is commonly found only during earlier attacks of the disease. It may affect a considerable length of ileum, or several discrete stretches of bowel, or even one short segment or it may be restricted merely to palpable thickening of Peyer's patches. Frequently with or without an inflammatory appearance of the bowel there is a small quantity of clear fluid in the peritoneal cavity.

The history is not particularly characteristic. In patients more often male than female, in most children beyond the years of infancy but the condition has been recorded at 10 months and at 2 years of age. The pain is essentially a general abdominal colic, often of extreme severity and very intense and alarming than the initial colic of appendicitis in childhood. Between spasms of colic there is entire freedom from pain. Even during the initial attack of pain the patient moves freely about, and violently sometimes, with a constant changing of position which would be unusual in acute appendicitis. As in appendicitis, when the patient is asked to indicate the site of most intense pain, he points to the right lower quadrant. In contrast to the patient with acute obstructive appendicitis, however, he cannot locate the site of maximum pain precisely, but indicates an ill-defined area on the right side. Nausea usually with vomiting, accompanies one at least, of the initial attacks. Diarrhea is exceptional. There has been quite often a recent sore throat or other upper respiratory infection.

Clinical examination provides no more specific evidence than does the history. The patient may seem little affected except by pain, or may be flushed and obviously feverish or pale. He is seldom or never prostrated or ominously motionless. If taken early in an attack, the temperature is elevated to 100° or even substantially higher and on the first day the

SURGERY OF THE ABDOMEN

here is an almost invariable leucocytosis of from 5,000 to 20,000 with 80 per cent or more of granular cells. As a rule the white count falls again on the second day—its elevation is quicker, higher and shorter-lived than in acute appendicitis. A bright red pharyngitis is not an unusual concomitant of nonspecific mesenteric adenitis but neither its presence nor its absence is highly significant. On abdominal examination tenderness is elicited in the right iliac fossa, higher and more medial than the usual tenderness of acute appendicitis. The lowest limit of tenderness is just below and to the right of the umbilicus. When the terminal (superior mesenteric) glands are widely involved a band of tenderness may be outlined as it extends upwards and to the left towards, and sometimes just beyond the midline of the epigastrium. The right lower abdominal muscles are nearly always in slightly higher tone than their fellows of the opposite side but rigidity is not maximal or if it is the muscles soften perceptibly under continued gentle pressure. Rebound tenderness is not unusual, particularly if the leaves of the mesentery or the serosa of the bowel are inflamed. One sign, shifting tenderness, is said to be suggestive though its absence is not significant. To elicit shifting tenderness the site of maximum tenderness is located while the patient lies supine, the position is then changed to the left lateral, and after a few minutes, if the sign is present the point of maximum tenderness will be found to have moved leftward to or beyond the midline. The sign depends upon postural displacement of the lower ileum with its mesentery, and is elicited only if the juxtaileal physical glands are inflamed. Rarely it may be positive early in acute appendicitis if the cecum is highly mobile. The enlarged glands are seldom palpable, even those at the root of the mesentery fixed against the background of the posterior abdominal wall and free fluid is not often of sufficient amount to be detected by percussion.

Confusion with appendicitis is less likely to occur in practice than seems possible when the symptoms and signs of the two conditions are compared on paper. The sharp spasms of colic with complete or almost complete freedom from pain between them, the rolling and kicking of the child in an attack, the high and medial situation of the rebound tenderness, the absence (if it is absent) of the rebound tenderness even at the point of shifting tenderness, the presence (if it is present) of shifting tenderness, relaxation under steady pressure of apparently rigid muscles and the history of previous typical recurrent attacks if these have occurred, all inspire confidence in a negative diagnosis of this is not appendicitis even if they fail to suggest the positive diagnosis of nonspecific mesenteric adenitis.

Differentiation of nonspecific from tuberculous mesenteric adenitis is not usually easy. In the latter condition leucocytosis is usually absent throughout the abdominal wall is almost completely lax, the enlarged matted glands are usually palpable and pain

or at least discomfort is more constant between attacks. If operation is not performed and doubt exists, it is not only more accurate but it serves better the interest of patient and of community to regard the condition as nonspecific unless there is clear evidence of tuberculosis elsewhere—in neck or chest, for example.

Other forms of mesenteric gland enlargement seldom produce acute abdominal symptoms. At operation malignant glands can usually be recognized by their character. In lymphadenoma and infectious mononucleosis glands elsewhere in the body are simultaneously enlarged. Even so it is wise in nonspecific adenitis to carry out a differential white count and the Paul Bunnell test.

The appearance in the glands, and more especially the appearances (when they are present) in the wall of the intestine are those of acute inflammation and strongly suggest a response to infection. The appendicular origin of nonspecific adenitis, however, is difficult to substantiate when it is remembered that the juxtaileal glands predominantly and in variously enlarged in the early case of adenitis are not found enlarged at operations for overt appendicular infections.

Nonspecific adenitis has been ascribed to the passage of a hypothetical virus through the mucosa of the intestine to its submucous lymphatic tissue, and thence to the mesenteric glands. Some support is lent to this hypothesis by the failure to culture bacteria from glands which are apparently the seat of acute inflammation. The coincidence or precedence of upper respiratory tract infection is an additional argument in favor of a more or less generalized virus infection. A relationship might be suggested between mesenteric lymphadenitis and the acute regional ileitis of Crohn. The gland enlargement in the mesentery of the affected bowel in regional ileitis is identical with that seen in nonspecific mesenteric adenitis indeed it is a nonspecific mesenteric adenitis. Conversely an early nonspecific mesenteric adenitis accompanied by a patchy pink inflammation of the serous coat of ileum and more significantly still, by an edema of all coats sharply demarcated from healthy bowel suggests an early, mild, self-limiting regional ileitis. It is a regional ileitis in the widest sense of the term. The identity or diversity of the two conditions could be proved only by the demonstration of the ultimate cause of one of them or the causes of both.

In the author's experience appendectomy does not affect the course of the disease which in any case is self-limiting and from which ultimate recovery seems to be inevitable. JOSEPH K. NARAT, M.D.

GASTROINTESTINAL TRACT

Hardt, L. L., Hufford, A. R., and Rabens, J. I. An Analytical Survey of 1,133 Patients Gastroscopically Examined. *Gastroenterology* 1945 4: 477

One or more gastroscopic and roentgenological examinations were performed on 1,132 patients who

cosin. One block was made through the anastomotic junction extending through the ulcer and the other section from the anastomotic ring free of gross ulceration.

In this study the gastrojejunal ulcer was found to be a disease of middle age. 93 per cent of the patients were men and 7 per cent were women. Pain was the most common symptom of gastrojejunal ulcer in this series of patients, being present in 86 per cent of the patients. The location of the pain varied markedly. In some patients the pain was epigastric or the same as that produced by the original duodenal ulcer. In others the pain extended downward to either side of the umbilicus or upward to the shoulder blades. At times the pain extended downward as far as the groin.

Hemorrhage was the most common symptom. Hematemesis and melena occurred in 32 per cent of the patients and melena alone in 42 per cent. The hemorrhages varied from massive single hemorrhages to repeated small hemorrhages. Vomiting occurred in 24 per cent of the cases.

Histological examination in this series showed that 81 per cent of the ulcers were on the jejunal side of the anastomosis, 3 per cent on the gastric side, and 3 per cent on the anastomotic line. The site of the remaining 13 per cent could not be determined.

In general, the ulcers resembled the peptic ulcers customarily seen. They were typically rounded and stamped out the mucosa and submucosa were absent over the base of the ulcer, and the muscular layers were completely replaced by fibrous tissue. Serosa was absent in all instances. It was concluded, however, that the absence of serosa was secondary in importance to the method of preparation of the slide. The anastomotic junction showed that the mucosa was well united in most instances but varied somewhat from the normal. Usually the gastric and jejunal mucosa ended abruptly but there were instances in which the jejunal glands were seen on the gastric side of the anastomosis. In a similar fashion gastric glands with acid cells were seen as frequently on the jejunal side of the anastomosis.

In the majority of cases a moderate degree of both gastritis and jejunitis was noticed. An attempt was made to correlate the severity of the clinical symptoms with the pathological changes, but relationship was evident. In some cases of severe gastrojejunitis only mild symptoms occurred whereas, on the other hand, in some cases of mild gastrojejunitis the clinical symptoms were severe.

SAMUEL J. FOSKLOV, M.D.

Ransom, H. K. Gastrojejunocolic Fistula. *Surg* 1937 945 18 177

During the 10 year period from 1934 to 1944 47 patients were treated by surgical operation for marginal or jejunal ulcer at the University of Michigan Hospital, Ann Arbor. Five of these 47 patients required an additional operation during this same period because of recurrent gastrojejunal ulceration and 1 patient was operated upon three times for

the same condition. Thus, a total of 54 operations was performed upon 47 patients. Of the above mentioned 47 patients, 8 (17%) had the serious complication of gastrojejunocolic fistula. It is with this latter group of cases that the present discussion is concerned.

A survey was made of all of the cases of gastrojejunocolic fistula at the University Hospital since its opening in 1925 and it was found that during 1925 to 1944, 18 unmistakable cases of gastrojejunocolic fistula due to ulcer had been encountered.

Gastrojejunocolic fistula almost invariably occurs as a complication of a marginal or jejunal ulcer at the site of a gastroenteric anastomosis for duodenal ulcer. The great majority of cases occur in instances of posterior gastrojejunostomy and much more often following simple short circuit operations rather than in cases of gastrojejunostomy associated with partial gastric resection. In every one of the 18 cases under discussion, duodenal ulcer was the primary lesion. It is a well accepted fact that marginal ulcer rarely occurs following gastroenterostomy for gastric ulcer and is almost unheard of following gastroenterostomy for carcinoma of the stomach. It is often stated that gastrojejunocolic fistula and gastrojejunal ulcer very rarely occur in women, the reason for this being the lower values for gastric acidity in women as compared with men. While the exact cause of marginal or jejunal ulcer is not known, the prevailing view is that these lesions most often occur in patients whose gastric acidity remains high following operation. This is much more apt to be true in gastroenterostomy or duodenal excision operations as contrasted with subtotal gastrectomy. In all of the authors cases, save 1 posterior gastroenterostomy was the primary operation which was followed later by a marginal ulcer.

It would be expected that prior to the onset of the fistula, symptoms of an anastomotic ulcer would usually be present. This, however, was not true in the majority of the cases herein reported as only 6, or one-third of the 18 patients gave such a history. The remaining 12 patients in this series apparently were relatively symptom free until the onset of the symptoms of fistula. In view of the mechanical nature of the lesion any great improvement in the state of nutrition prior to operation is difficult or impossible. Preoperative laboratory work should include the determination of serum proteins and prothrombin clotting time.

The surgical operation in all cases consisted of a one stage procedure. In 10 instances a restorative type of operation was performed whereas in 4 cases, gastric resection was included. There was 1 post-operative death in each group, or a mortality of 14.3 per cent for the entire series.

Follow up studies showed that all patients who survived operations including gastric resection had good results, whereas only 4 of the 9 patients surviving the more conservative operative procedures remained free of ulcer symptoms. Three of the 5 patients with recurrent ulcer subsequently required

SURGERY OF THE ABDOMEN

further surgical therapy. No deaths occurred among these patients who later required reoperation.

While gastric resection is ordinarily desirable at the time of the operation for the repair of the fistulas, it is not always feasible or safe. Restoration of the tract to normal, therefore, is a useful procedure in certain cases. This was true particularly in these cases because many of the original gastroenterostomies were performed upon meager indications as judged by present day standards. If further surgery for recurrence of the ulcer becomes necessary later a subtotal gastrectomy can be carried out upon a patient in good condition with a very low mortality.

Gastrocolic fistulas due to primary disease of the stomach or colon are discussed. The patients present problems in preoperative care and in certain matters of surgical technique which are similar to those just discussed.

A small group of gastroenteric fistulas due to surgical errors at the time of the original operation for ulcer is considered briefly. *JOSEPH GUTER, M.D.*

Berkman, J. M., and Heck, F. J.: Symptoms following Partial Gastric Resection. Gastroenterology 1945 5 85

The authors present a résumé of their observations of the unfavorable symptoms exclusive of recurrent ulceration which may follow partial gastric resection. The cause of these symptoms has not as yet been explained satisfactorily. At the present time however the most commonly accepted explanation of the postprandial symptoms known as the dumping syndrome, is jejunal distention.

The inanition which may occur as a result of the postprandial symptoms may be overcome by placing the patient on a high protein diet, first with a small amount of bulk and then a gradual increase of the bulk to that amount represented by 2500 calories. By this method without further increase of bulk a diet with a caloric value of 3200 calories may be reached which will insure a progressive increase in weight without an increase of the severity of the postprandial symptoms.

A group of patients who have experienced nausea to a sufficient degree to prevent the eating of several nonconsecutive meals each week has been observed. The nausea was not associated with postprandial symptoms and did not follow the taking of food.

Also a number of patients have been seen who although they had experienced no symptoms after partial gastric resection had found it impossible to eat enough in the usual three daily meals to regain the weight lost after operation. By the dietary method described a progressive gain in weight was brought about without postprandial discomfort.

In some cases hypochromic microcytic anemia developed after partial gastric resection and failed to respond to the usual treatment for hypochromic anemia. The value for hemoglobin improved after a high protein diet with a caloric value of 3200 calories had produced an increase in weight.

CHARLES B. ROW, M.D.

Lerner, N. Robinson, H. W., Grishelmer, E. M., and Oppenheimer, M. J.: Effects upon the Small Intestine of Rapid Intravenous Injections of Casein Hydrolysate. Gastroenterology 1945 5 201

The possibility that amino acids when used intravenously may alter intestinal motility and hence endanger new suture lines prompted the authors to study the reaction of the mixture of acids used in the region of pH 5 and may produce a temporary lowering of the blood pH when introduced into the blood stream in sufficient quantities at a rapid rate. The rôle of change in pH on motility is also in need of investigation and the authors study includes such considerations. The duodenum was selected because of the frequency of surgical intervention in this area. Studies were carried out on patients with normal gastrointestinal tracts and on dogs with and without anesthesia.

The authors discuss the methods used and the results obtained in (1) anesthetized dogs (2) patients with normal gastrointestinal tracts and (3) dogs recently operated upon.

In conclusion the authors state that rapid intravenous injections of casein hydrolysate produce a venous hypermotility or change in pattern of duodenal hypermotility or change in pattern of motility in anesthetized dogs. This hypermotility is not accompanied by significant changes in pH of the blood plasma. The blood glucose concentration is elevated. Neither hypermotility nor hyperglycemia is prevented by atropine or vagotomy. New intestinal suture lines are not disturbed by the hypermotility during parenteral use of casein digest. Rapid intravenous injections of casein digest in unanesthetized humans change the character of contractions and often accentuate tonus changes. Subjective sensations and changes in motility were correlated in only half of the cases studied.

EMIL C. ROBINOW, M.D.

Falk, H. C., and Hochman, S.: Intestinal Injury and Fecal Fistula in Gynecological Surgery. Am. J. Surg. 1945 70 176

The small or large intestine may be injured during any gynecological laparotomy, most often on the separation of adhesions found between the intestines, the pelvic viscera and the abdominal wall. These adhesions may be the result of pelvic inflammatory disease or of previous operations. This is shown by the high incidence of fecal fistulas following surgery for pelvic inflammatory disease.

There were 42 cases of intestinal injury observed by the Gynecological Service of the Harlem Hospital from 1928 to 1943 where more than 80 per cent of the patients operated upon have some degree of pelvic inflammatory disease. During this period of 16 years 5055 laparotomies were performed. The known incidence of intestinal injury was therefore 0.83 per cent.

The intestines may be injured on opening the peritoneal cavity. This type of injury as a rule is

detected and repaired immediately. Such accidents are more common in patients who have had a previous laparotomy. In this series there was only 1 such case. No fistula followed. The bowel may also be lacerated in cutting across the vagina in a total hysterectomy if the rectum is adherent to the posterior wall of the cervix. There was no such accident in this series. Injury to the intestines may also occur in the separation of adhesions between two loops of bowel, the intestines and pelvic organs, or between the intestines and the abdominal wall.

Two types of adhesions are found: those caused by a previous laparotomy in which the intestines and omentum may be firmly matted together with the pelvic organs, and those caused by pelvic inflammatory disease, gonorrhea produces few adhesions except at the fimbriated end of the tube. The adhesions between the intestines and the tubal wall are usually friable, thin and flimsy and easily separated. When the pus has spilled into the cul-de-sac, the adhesions between the sigmoid tube, and posterior wall of the broad ligament are very dense. Here the separation is usually done blindly (without vision) and the large bowel may easily be injured; such an injury may not be recognized. There were 7 such cases of injury in which the sigmoid was densely adherent to a tubo-ovarian abscess or pyosalpinx.

Usually the intestinal injury is seen and recognized at the time of operation. There were, however, many cases in which the intestinal trauma ultimately caused necrosis of the bowel, but no injury had been recognized at the time of operation. As a result, a fecal fistula or fatal peritonitis occurred post-operatively.

In pelvic inflammatory disease of pyogenic or tuberculous origin, degenerated or infected fibroids, endometriosis, ovarian and tubo-ovarian abscesses and malignancies the adhesions encountered are very dense. In the separation of these adhesions to isolate the pelvic structures, the intestines are easily injured.

The most reliable index of acuteness of pelvic inflammatory disease is the sedimentation rate.

Among the 18 cases of fecal fistula, there were only 4 in which the sedimentation rate was longer than 30 minutes.

The 42 cases of intestinal injury were divided as follows:

1. Injury detected and repaired during operation without fecal fistula formation—22 cases.

2. Injury detected and repaired at operation, with the development of fecal fistula—3 cases.

3. Injury not detected at operation, with result ing fecal fistula—15 cases.

4. Injury not detected at operation, with result ing peritonitis and death—2 cases.

1 and 2. Injury detected and repaired during operation—25 cases. In 25 or 59.5 per cent, of the total number of 42 cases, injury to the intestines was detected and repair was accomplished during operation.

The prognosis in intestinal injury is largely dependent upon recognition and repair at time of operation.

Repair of intestinal injuries was accomplished by two to three rows of locked, interrupted, or continuous running sutures of No. 00 chromic catgut or Pagenstecher thread.

In recent years 10 gm. of a sulfonamide were placed into the pelvis and over the repaired area.

The treatment of fecal fistulas low in the intestinal tract, as in the terminal ileum, sigmoid, or rectum, is much less urgent than that of those located in the duodenum or upper jejunum because of the slight loss of fluids, food and enzymes. Fistulas of the large bowel or terminal ileum usually heal spontaneously. Sufficient time should be allowed for the fistulas to close spontaneously before surgery is attempted.

HARRY W. FINE, M.D.

Pugh, H. L.: Regional Enteritis. *Ann. Surg.* 1945, 121: 845.

Crohn, Ginsburg, and Oppenheimer in 1933 published the original article describing the clinical entity known as regional enteritis. This article was so accurate that all the literature contributing to the subject in the past 13 years has subtracted nothing from it. The original title was "Terminal Ileitis." The author has substituted the word "regional," since "terminal suggested agonal and enteritis has been substituted for "ileitis" since not infrequently other parts of the small or large bowel have been affected. Numerous names have been suggested for this condition, among which have been terminal ileitis, regional ileitis, regional ileocolitis, regional enterocolitis, segmental enteritis, nonspecific granuloma, infective granuloma, chronic cicatrizing enteritis, pseudocancer, Crohn's disease, and regional enteritis. The last mentioned term is the most popular and comes nearest to being true and appropriate.

The authors present a series of 17 cases, and furnish some of the special observations which have been made by a variety of contributors.

It is believed that this disease has existed for centuries. W. J. Mayo in 1893, Combe in 1913, and Moschowitz in 1923 described cases in the literature which probably were regional enteritis. There appears to be a definite increase in the incidence of the disease which cannot be entirely explained by the improvement in diagnosis.

The etiology of this condition is still unknown. The theory that Koch's bacillus may be the causative agent has been disproved. It is not improbable that there may be some correlation with mesenteric lymphadenitis. An allergic tie-up is still fanciful. Several writers have reported that the malady has a predilection for Jews, particularly at an early age.

It has been claimed that the disease is more prevalent in Eastern cities, and it is probable that there may be a seasonal variation in the tendency to acute exacerbation of the disease. Crohn suggested the disease may have a familial tendency. The disease is more likely to appear between the ages of

SURGERY OF THE ABDOMEN

15 and 40 and the majority of statistical reports indicate a slightly greater frequency in males than females.

Knowledge of the early stage of regional enteritis remains conjectural, since it is seldom recognized until thoroughly advanced. It probably begins as a proliferative process in the interstitial structure of the bowel wall and progresses to a cicatrizing granularomatous lesion. The mucosa becomes ulcerated as the bowel thickens possibly from interference with the blood supply, or from an infective process (virus or bacterial). Fibrosis develops and the bowel wall thickens. This, plus the contraction of cicatrizing thickens, narrows the lumen until obstruction may ensue. The adjacent mesentery becomes thickened and discrete. Both the bowel and the mesentery become edematous. With progress of the disease the ulcerated areas may perforate and lead to abscess and fistula formation. These fistulas may communicate with loops of small bowel, large bowel, bladder, or even through the abdominal wall. Some writers believe that the disease passes through four stages, namely (1) acute, (2) irritative (3) obstructive, and (4) fistulous.

Almost any part of the intestinal tract from the jejunum to the sigmoid may be involved, with the terminal ileum the favorite site. The disease not infrequently extends past the ileocecal junction and invades the cecum. Skip areas in several portions of the bowel in the same person may be involved with healthy segments intervening.

The disease is chronic and is characterized by periods of exacerbation and remission. The weight of evidence and opinion indicates that spontaneous cure, if it ever occurs, is rare.

The involved bowel during acute stages of the disease is swollen, hyperemic, and inflamed. The mesentery is swollen, edematous, and likewise inflamed with lymph nodes varying in size from that of a pea to a walnut. Gross corrugations extend from the mesenteric border and tend to encircle the bowel and give it a cobblestone appearance. It is not uncommon to see a considerable accumulation of serosanguineous fluid within the peritoneal cavity during the acute phase. The involved bowel by contrast during the quiescent or remission stage, remains heavy, thickened and leathery—devoid of its normal flexibility and distendability. As the hyperemia subsides the plastic exudate organizes and forms dense fibrous bands and adhesions.

Histologically the affected bowel reveals a marked fibrosis and thickening of mucosal and submucosal layers. The entire structure of the bowel wall shows a mononuclear infiltration. Giant cells are not uncommon and frequently lead to a false diagnosis of tuberculosis.

The symptoms depend on the stage, location and severity of the disease. The three cardinal symptoms are intermittent cramplike abdominal pain, intermittent diarrhea and loss of weight. Nausea is not uncommon and when present is usually accompa-

nied by diarrhea. Anorexia is frequently seen. As the pain is usually in the lower right quadrant it is not surprising that 50 per cent of the cases have been diagnosed as acute appendicitis and operated on for that. Hemorrhage from the bowel occasionally occurs.

Anemia is a common sign of regional enteritis and some temperature elevation particularly with acute exacerbations is common. The temperature may be normal during remissions or may show a slight rise in the afternoon. The white blood count may be elevated to 20,000 in the acute phase or may fluctuate between normal and that commonly associated with acute appendicitis. The blood sedimentation rate is usually elevated. A mass with tender dominal examination a boggy mass may be palpated in the right lower quadrant. A mass with tenderness is sometimes palpated on rectal examination. X ray examination is frequently referred to as the most important diagnostic sign. Intestinal fistulas or the narrowing of the luminal shadow in the terminal ileum (Kantor's string sign) may be demonstrated. When present, this sign is practically pathognomonic of regional enteritis.

The author considers the points mentioned important in differentiating regional enteritis from acute appendicitis, intestinal tuberculosis, amebiasis, diverticulitis, and chronic ulcerative colitis.

In the author's series of cases the following complications occurred in order of their frequency: (1) involvement of segments of the large bowel apparently as direct extension from involved small bowel segment (6 cases) (2) positive Kantor's sign (3) fistulization (6 cases) (4) fistulous communication with abdominal wall—external fistulae (4 cases) (5) the abdominal wall—external fistulae (4 cases) (6) skipped areas in the small bowel (3 cases) (7) apparent subsidence of symptoms and absence of roentgenological signs without operative interference (3 cases) (8) hemorrhage (1 case) (9) recurrence after operation (1 case) (10) fistulae or fissure in ano (1 case).

Of the 3 cases which cleared up without definitive surgery the first at operation showed six areas in the jejunum and ileum typical of regional enteritis with healthy bowel from 1 to 3 feet in length between the diseased segments. Because of the extent and distribution, the patient's abdomen was closed without resecting any bowel. Postoperatively penicillin was given with a rapid improvement in symptoms and negative x ray of the bowel. The second case was diagnosed as regional enteritis after the patient had been operated on for acute appendicitis by another surgeon. Six months later at celiotomy scarcely any evidence of the former acute process was found. The third case was a similar condition which improved so much clinically that a second operation was not considered warranted.

Penicillin was used in 5 cases, all of which showed prompt clinical improvement. While it may be speculative it is believed the drug was a definite factor in the amelioration of symptoms.

The literature preponderantly favors surgery as the treatment of necessity. Elliott Cutler of Harvard University still believes the disease should be treated medically unless certain complications arise. The author believes that surgical treatment is by all odds preferable. All seem to agree that in the acute form of the disease no surgery should be instituted unless some complication such as obstruction makes emergency intervention imperative. It is inadvisable to remove a normal appendix in the presence of enteritis lest a fistula develop. If obstruction is present, most surgeons agree that a short-circuiting operation such as an ileotransverse colostomy should be done. If the operation may be classed as elective, the surgical proponents may be classed in two groups—those who advocate a 2 stage procedure and those who advocate a 1 stage procedure. The author resected the lesion and did an ileotransverse colostomy in 1 stage in all but 2 cases, in 1 of which a 2 stage and in the other a 3 stage procedure was carried out.

There was 1 death in the series. A resection of the right colon was done with an end-to-side ileotransverse colostomy. The patient died 4 days later of urinary suppression, the cause of which was undetermined, but attributed to sulfa drug sensitivity. At autopsy there was no blockage of the uriniferous tubules or peritonitis. ROBERT R. BIGGLOW, M.D.

Centeno, A. M.: Diverticula of the Duodenum (*Diverticulos del duodeno*). *Praxis med. argent.* 945 32 1829.

The clinical and roentgen pictures of ulcer of the duodenum are very well known but those of other diseases of the duodenum are not so well known. As a contribution to this subject the author discusses 55 cases of diverticulum of the duodenum seen at the National Dispensary for Diseases of the Intestinal Tract in Buenos Aires. Roentgenograms of a number of the cases are given.

The first case of diverticulum of the duodenum was described by Chomel in 1710. The first stage in the history of the disease was devoted to autopsy descriptions, the second to roentgen examination and the third to clinical study. Case described the first roentgen examination of the condition in 1903 and Forsell and Kay performed the first surgical operation for its treatment in 1915. Including the 55 cases discussed in this article the total number of cases seen in Argentina has been 158.

These diverticula are most frequent in the second portion of the duodenum, then in the third portion and then in the fourth portion—they are rare in the first portion. Those in the second portion are apt to press on Wirsung's duct and the common bile duct, and cause icterus and the symptoms of pancreatitis. Those of other portions of the duodenum often do not cause any symptoms at all and may be found only on autopsy. Among the author's 55 cases 36 were in the second portion. In only 1 of the cases was the duodenal diverticulum associated with diverticulosis of the colon. These diverticula are

generally solitary. In only 2 of these cases was there a double diverticulum.

These diverticula may be congenital or acquired. In the congenital cases all the layers of the intestinal wall are involved but in the acquired cases the mucosa and submucosa herniate through the muscle layer. The diverticula generally occur in the middle period of life and are about twice as frequent in males as in females. They are frequently complicated by other pathological conditions, and it has been claimed that any uncomplicated diverticulum of the duodenum is symptomless. Of the author's 55 cases, 23 or 41.8 per cent were associated with other diseases: 7 with cystitis, 9 with ulcer of the duodenum, 3 with cancer of the stomach, 2 with ulcer of the stomach, 1 with diverticulosis of the colon, and 1 with diaphragmatic hernia.

The symptoms such as pain and vomiting, are not pathognomonic and roentgen examination is required for definite diagnosis. Icterus may be caused by infection but is not frequent as this part of the intestine does not become infected easily.

Uncomplicated cases should be given medical treatment designed to evacuate the diverticulum and prevent dilatation and infection. This may be accomplished by frequent change of position, the administration of antispasmodics and irrigation of the stomach. Small doses of sodium sulfate or magnesium chloride stimulate the duodenal motility and aid in evacuation. Ten gram doses of bismuth carbonate, kaolin, or magnesium trisilicate may be given for inflammation. If surgery is necessary it consists of invagination or resection. If there is icterus without calculus medical drainage of the bile ducts is preferable.

AUSTIN G. MORRIS, M.D.

Iludinarah, T. A., Stewart, A. W. and Morrison, B.: Resection Operation for Gangrenous Intussusception in Infants. *Brit. M. J.* 1915, 1: 38.

When in an infant an acute intussusception becomes irreducible and gangrenous, not only is the choice of a suitable operation difficult but the results are usually bad. The operation commonly chosen in these cases is either resection of the gangrenous mass with end-to-end or lateral anastomosis, or enterolization of the mass with the formation of an enterostomy with a later attempt to close this if the child survives. Suture of the proximal part of the intussusception to the intussusceptum has also been suggested, the gangrenous mass sloughing and passing per rectum. These operations are far from satisfactory—very few children survive.

In view of these results the authors have recently chosen to treat the irreducible gangrenous intussusception by a rod fixation of the Mikulicz type of resection and are able to report a success. The danger of generalizing from a case is recognized, but the results in these 2 cases were so much better than those experienced with other methods that this report seems justified. At this point, however,

SURGERY OF THE ABDOMEN

it should be made clear that no major operation of this sort to an infant will be successful unless the child is given special preoperative and postoperative treatment by those who are experienced in modern pediatric methods and can judge from hour to hour what measures are required to be taken. A note by Brenda Morrison on these measures is included in this article.

The Mikulicz type of resection recommended is made possible in infants because at that age the cecum, ascending colon and transverse colon are very mobile. In both cases it was found easy after a small incision of the peritoneum on the outer side of the intussusception to mobilize the mass and to bring it out of the abdomen with very slight trauma. The next steps of the operation could then be performed expeditiously and with relative ease.

The operative procedure followed in both cases was similar. The preliminary attempt at ordinary methods of reduction having failed the intussusception was found to be gangrenous and some form of resection was therefore necessary. The viable portions of the ileum and colon were quickly joined together in the usual double barrelled Mikulicz colostomy method, by two layers of continuous catgut sutures, and the abdominal incision was closed around the bowel by interrupted sutures. The condition of both cases at the end of operation was satisfactory. After 6 days the spurs were crushed and removed by the ordinary Mikulicz method with the small crushing clamps. Six days later on the twelfth day after operation the stomata were closed after the bowel ends had been freed and turned in.

The first patient has now made an excellent and permanent recovery. The patient has gained satisfactory weight, and a slight tendency to diarrhea, due to loss of the ileocecal junction has cleared up. The second patient made an excellent recovery after operation, and it is anticipated that this patient also will return to normal health.

JOHN E. KIRKPATRICK, M.D.

Newton F. C. and Blodgett J. B. Succinylsulfa-
thiazole and Intestinal Suction in Surgery of
the Large Bowel. *Surgery* 1945 18: 300

There have been two recent important improvements in the operative preparation of patients for surgery of the large bowel. The first is the use of the Miller Abbott tube and the second is the use of chemotherapy to minimize the number and virulence of organisms within the lumen of the bowel. This article is a statistical report of the authors' experience at the Peter Bent Brigham Hospital, Boston, with these two adjuncts to colon surgery. It compares the results in a series of consecutive cases of resection of the large bowel prepared by these two techniques with a series in which they were not used.

Until recently proximal colostomy has been widely used in preparing patients for resection of the large bowel. The advantage of preliminary colostomy is that, preoperatively the bowel is relieved of distention and may regain its function and the

distal lumen may be nearly emptied of its contents and postoperatively the site of anastomosis is kept at rest and the risk of blowout at the suture line from increased intraluminal pressure due to temporary obstruction at the anastomosis is minimized.

A series of 114 cases of resection of the large bowel was studied. The general preoperative and postoperative care was the same in all except that in the test group (36 cases) succinylsulfa-thiazole was used before the operation and postoperative intestinal suction were carried out. In the control group (78 cases) primary colostomy without chemotherapy was the routine in resections with restoration of the continuity.

The Mikulicz type of resection was not required in any cases of the test group.

The following data are of statistical significance in the comparison of the two groups.

1. The gross incidence of complications was reduced from 58 to 45 per cent.
2. The gross mortality was reduced from 19 to 3 per cent.

3. When similar operative procedures (resections and anastomoses) are compared it is found that the incidence of postoperative infection is reduced from 43 to 6 per cent and the mortality is reduced from 22 to 3 per cent.

The use of intestinal suction and succinylsulfa-thiazole in the preoperative and postoperative care of patients who undergo resection of the large bowel has a definite effect in reducing the incidence of postoperative infection and mortality.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Mirizzi P. L.: Fourteen Years of Experience with
Operative Cholangiography (Colangiografía
operatoria catorce años de experiencia). *Prensa Médica*
Buenos Aires 1945 32: 1887

The first cholangiography practiced during operation was performed June 18, 1931 on a patient with calculous hydrops of the gall bladder. The author reviews his experience with the method in the 14 years since that time illustrating his findings with case histories and cholangiograms.

The method has demonstrated that there is peristalsis of the common duct and that the hepatic duct contracts totally or partially both important factors in the filling and emptying of the gall bladder.

In addition to contributing to our knowledge of the physiology of the bile tract, cholangiography is extremely useful in the diagnosis of many pathological conditions of this tract and has contributed greatly to better the surgical technique in operations on it. It gives the surgeon a so much clearer picture of the tract that he can avoid complications that were formerly frequent such as anatomical disturbances, residual lithiasis, cicatricial stricture of the hepatocommon duct and anomalies.

The important thing now is to help to generalize the use of the method rather than to discuss its value which has been proved beyond doubt.

AUDREY G. MORGAN, M.D.

Cole, W. H., Irenius, C., Jr. and Reynolds, J. T.:
The Use of Vitallium Tubes in Strictures and
Absence of the Common Bile Duct. *A. Surg.*
1945 122 490

The most serious stricture of the common bile duct and the one most difficult to correct is total "absence" of the common duct which unfortunately is more common than the short stricture with sufficient proximal and distal ends for approximation. In 10 of this series of 23 cases of stricture or absence (including a carcinoma of the common hepatic duct) no duct could be found except the stump at the hilus of the liver. In this group the use of the vitallium tube was adopted and a few principles were established which helped the authors to arrive at a method of treating this defect which yielded fairly good results.

The method of repair of stricture depends upon the type of defect encountered. Defects can be divided into four major groups from the standpoint of the technique indicated: (1) local stricture of the common duct, (2) stricture or absence of the terminal end of the common duct, (3) absence or stricture of the common hepatic duct, and (4) absence of the common and common hepatic ducts. In general, the utilization of rubber tubes in repair has not given satisfactory results largely because they are usually passed within a short time. If they are retained there is a slightly greater tendency for the precipitation of bile salts in the lumen than in the lumen of vitallium tubes.

All (15) of the rubber tubes which the authors have inserted have been passed. Of 14 vitallium tubes which they have inserted 3 have been passed. Although the discussion in this presentation is related to the use of vitallium tubes in strictures or absence of the common duct, it is emphasized that whenever possible anastomosis should be made with no more than temporary intraluminal support. The bridging of defects by the insertion of a T tube serves the purpose of function quite well.

In stricture or absence of the terminal end of the common duct the authors are of the opinion that transplantation of the duct into the duodenum should be the first operation tried.

The third type of defect is more difficult to repair than the first two largely because anastomosis of the duct at the hilus of the liver cannot be achieved with ideal technique. The insertion of a vitallium tube with the funnel end projecting into the stump of the common hepatic duct at the hilus and the lower end protruding into the common duct, as first performed by Clote is the procedure of choice.

When no remnants of the external duct can be found the problem of repair becomes much more difficult. The only possible method of repair is to anastomose the stump of the common hepatic duct

at the hilus of the liver to a loop of intestine. Its ability to obtain a good anastomosis and the lack of an appreciable amount of duct wall are largely responsible for the poor results in plastic procedures when no duct can be found. Cholangitis is the pathological lesion feared in any repair of this type, while an even greater danger is the development of multiple abscesses of the liver. The authors are of the opinion that in addition to the tendency for stricture formation to occur reflux of food and intestinal secretion into the intrahepatic ducts is very important in the development of cholangitis. Therefore they attempted mechanically to prevent reflux of food up through the line of anastomosis into the liver by isolation of the area from the food stream.

Two methods of reconstruction were employed to accomplish this: (1) anastomosis of the hepatic stump to an arm of the jejunum after the Roux principle and (2) attachment of the hilus to a loop of jejunum in which an anastomosis is performed between the two loops at a distance from the hilus anastomosis. Better results were obtained by anastomosis according to the Roux principle with the single arm of jejunum. The stump of the hepatic duct at the hilus is approached by staying close to the ventral surface of the liver and working from the lateral side. After the stump is located the jejunum is severed about 2 foot or more from the ligament of Treitz. The distal end is closed by inversion with a single line of continuous catgut suture. The end of the proximal loop is then anastomosed to the distal loop at least 5 feet from the end which is to be attached to the duct at the hilus of the liver. If the mesentery of the distal loop of jejunum is not long enough to permit approximation to the hilus of the liver without tension an opening is made in the mesocolon and the arm of jejunum is drawn up through this opening. The opening of the common hepatic duct at the hilus is dilated to a size which will allow introduction of the funnel end of the vitallium tube. The right and left hepatic ducts can be located by probing and occasionally the duct will be found to divide so close to the hilus that the ordinary tube will be blocked by the septum between the ducts. Under such circumstances a tube with a Y-end should be used so that each duct is cannulated. A purse string suture of silk is placed around the end of the duct and the tube inserted. Tying the suture should anchor the tube securely. A purse string suture is then applied around the center of the line of closure at the end of the arm of jejunum. A small opening is made about 1 inch from the end of the jejunum and with a curved Pean forceps inserted into the jejunum and out through the closed end, the end of the vitallium tube is grasped and pulled into the end of the intestine. The purse string suture is then tied. Interrupted sutures anchor the end of the intestine against the hilus of the liver. Two or three valves or baffles are made in the arm of the jejunum to prevent upward reflux of the intestinal contents.

Anastomosis of a loop of jejunum to the stump of the hepatic duct at the hilus requires less operating time than the anastomosis of the Roux type but 3 of 4 patients surviving this type of operation developed chills and fever after a variable time. This type of anastomosis is not recommended unless an effective valve or baffle is placed in both arms of the loop particularly on the proximal side. An enterostomy must be made between the two loops of intestine at least 12 inches away from the anastomosis between the duct and the jejunal loop.

The authors have inserted 14 vitallium tubes in the treatment of stenosis or absence of the common duct. In 5 cases the Roux Y principle was used. The results in 4 of these 5 patients were from good to excellent. The results following the use of a loop of jejunum for the anastomosis were not so satisfactory. Chills and fever were common. In 3 patients the proximal loop of the jejunum was interposed at a later operation following which there was abrupt cessation of the chills and fever in 2 patients. The operative mortality for 14 cases was 14.3 per cent.

It is concluded that the best operation in the type of patients in whom no common duct can be found is anastomosis of the stump of the hepatic duct to a single arm of the jejunum which is at least 24 inches long and the walls of which have been folded to produce valves or baffles. Prevention of obstruction by the use of a tube did not prevent the occurrence of chills and fever unless reflux of the food was prevented by the operative procedure. The vitallium tube has a definite place in reconstruction of strictures and absence of the common duct, but it is indicated primarily in patients in whom no common duct whatsoever can be found and in patients in whom the common hepatic duct cannot be found.

JOHN L. LINQUIST M.D.

Brunschwig, A. and Bigelow R. R. Advanced Carcinoma of the Extrahepatic Bile Ducts; Cholangiocholecystocholedochectomy. Ann. Surg. 1945 123 535

Seven patients presenting advanced carcinoma involving most of the extrahepatic bile passages and extending into the gall bladder and without apparent diffuse peritoneal spread or hepatic metastases, were subjected to radical resection of these ducts and of the gall bladder. In one instance a portion of the head of the pancreas was also resected. The purpose was to ascertain if palliation might be afforded in this rather hopeless condition if most, or all, of the macroscopic neoplasm was removed.

The procedure was a cholangiocholecystocholedochectomy was carried out under continuous spinal anesthesia supplemented by ethylene and ether if necessary. It consisted of

- 1 A high midline or reverse-L incision
- 2 Aspiration of the gall bladder if necessary to facilitate access to the porta hepatis.
- 3 Dissection of the gall bladder from the liver bed and if it was extensively involved by carcinoma,

wedge shaped resection of a portion of the liver about the gall bladder

4 Application of hemostats to the gall bladder and traction upon it to elevate the mass in the porta hepatis

5 Isolation of the lower segment of the common duct behind the duodenum after mobilization of the duodenum and head of the pancreas from the lateral side

6 Transection of the common bile duct behind the duodenum, and incisions into the head of the pancreas to mobilize portions invaded by carcinoma.

7 With the hemostat applied to the upper 1/2 of the transected common bile duct, dissection was carried out upward to free the involved extra hepatic bile ducts from the surrounding areolar tissue. This is the most precarious stage of the operation because of the danger of opening the portal vein or hepatic artery

8 Transection of the right and left hepatic ducts at or just beyond their emergence from the liver and removal of the specimen.

9 Insertion of T tubes or catheters so as to create a junction between one or both hepatic ducts and the common duct stump

Four patients survived the operation from 3 months to 1 year. The icterus cleared or was partially relieved in all. There was some palliation in all patients, but in 1 the general condition was deteriorating.

The results achieved by radical excision in these patients with advanced extrahepatic biliary carcinoma do not permit alteration of the very pessimistic outlook concerning this situation. Although survival was ameliorated in those surviving the operation, survival was probably not significantly enhanced. The possibility of a radical procedure in this region is demonstrated, and its performance in the presence of more localized carcinoma might increase the opportunity for more patients to survive of such patients. On the other hand, the frequency with which icterus may develop in the course of this disease adds greatly to the difficulties of diagnosis at an early stage.

JOHN L. LINQUIST M.D.

Wechsler H. F. and Weimer J. L. Lithiads. A Report of 2 Cases. Trans. Adults. Gastroenterology 1945 5:1

The authors believe it is commonly known that pancreatic calculi are found only in patients of 40 and that the condition is considered as a possibility among the younger age group. However, the authors report one in a white male 28 years of age. Both white male 27 years of age. Both patients had a long history of digestive abdominal pain the symptoms of which began at 8 and 10 years respectively. The disease is slow and progressive and that the demonstration of calc

that the symptoms had been present for a considerable period of time. The etiology is unknown and the authors state that alcoholism cannot be the sole cause of the disease.

Both of the patients had suffered since childhood with intermittent attacks of upper abdominal pain associated with bloating, nausea, and vomiting. The pain was not relieved by eating and it was aggravated by fried or greasy foods, and by a large meal. Between attacks both patients complained of a dull soreness in the epigastrium, especially on arising in the morning. Neither of the patients had lost weight. There was no glycosuria nor jaundice, and no evidence of hyptic dysfunction.

The roentgenological findings in both cases were classical and of the most common type of pancreatic lithiasis. It is emphasized that patients with this condition may have a history of abdominal symptoms dating back to childhood.

EMIL C. ROSTRICK, M.D.

Marcheroni H. A., Rosal C. and Clerici, L. E.: Failure of Surgical Treatment in a Case of Thrombophlebitis of the Splenic Vein (Tromboflebitis de la vena esplenica. fracaso del tratamiento quirurgico en una observacio.) *Rev. As. Med. Argent.* 943 59 20 5

Thrombophlebitis of the splenic vein alone is quite rare. It may be primary due to blood diseases or primary phlebosclerosis; it may be secondary following compression by cysts or tumors, or from propagation of neighboring infections, such as puerperal infection, appendicitis, or ulcer of the stomach; or it may be brought about by retardation of the circulation in general diseases such as cancer, malaria, or tuberculosis, or in a local cirrhosis of the liver.

It is important to differentiate between phlebitis of the splenic vein and that of the portal vein because surgery is indicated in the former and contraindicated in the latter. In phlebitis of the trunk of the portal vein there is at first an ascites which later disappears, hemorrhages from the hemorrhoidal and possibly the splenic arteries, and a collateral circulation around the umbilicus. When these signs do not exist the phlebitis is probably splenic. There is apt to be repeated vomiting of blood in both forms. Diagrammatic sketches of the two forms are given. On opening the abdomen the surgeon should confirm the probable clinical diagnosis by examination of the portal and splenic veins.

Eppinger operated on 14 cases of phlebitis of the splenic vein with the following results: 4 patients lived more than 10 years, 3 lived more than 5 years, 3 died soon after the operation, 2 died in the course of 2 years, and 3 were well a year and a half after the operation but were not examined further.

The authors describe a case in a girl of 13 years who for several years had had repeated attacks of vomiting of clots of dark red blood. She was an intractable patient, and examination and treatment were difficult. On admission she had fever and a

splenic anemia with very great enlargement of the spleen, which decreased in size after each hemorrhage and after the injection of adrenalin. Splenectomy was performed January 19, 1944. On February 3, 1945 she began to have colicky abdominal pain, followed by copious hematemesis and a small rapid pulse. She died on the night of February 3. Histological examination showed that there was thrombophlebitis of the trunk of the portal as well as of the splenic vein.

AUDREY G. MONROE, M.D.

Bukh, H., and With, T. K.: Splenectomy in Chronic Nonleukemic Myeloid Splenomegaly with Report of a Case with Osteoclerosis. *Acta chir. scand.* 943, 91 307

Chronic nonleukemic myeloid splenomegaly is briefly described and a personal case in which splenectomy was performed is presented.

The risk of performing splenectomy on false indications in this disease is stressed, and a survey of 54 cases of chronic nonleukemic myeloid splenomegaly from the literature in which splenectomy was performed is given.

As the result of the operation in these cases very often is death and true benefit to the patient is seldom achieved, splenectomy should be carried out for this disease only on certain narrow indications.

To avoid splenectomy on false indications, splenic puncture is necessary. It may be carried out with very small risk with the technique of Emile-Weli and his collaborators. In all cases of Banti's disease (even apparently typical ones) in hemolytic jaundice and in essential thrombopenic purpura, splenic puncture should be carried out before splenectomy is decided upon.

MISCELLANEOUS

Hudson, H. N. G.: Closed Intra Abdominal Injury. *Br. M. J.* 943 4 9.

Three cases of visceral injury resulting from three different types of blunt force to the abdomen are reported. In one instance the jejunum was ruptured as the result of a sharp glancing blow on the relaxed abdomen. In another case rupture of the full stomach by force of a powerful crushing nature was fatal. In the third case the spleen was ruptured as the result of a sudden kick on the elastic overlying ribs.

WALTER H. NADLER, M.D.

Ewing, W. M., and Betts, R. H.: Thoracoabdominal Injuries. *Ann. Surg.* 943 793.

Thoracoabdominal injuries have shown a uniformly high mortality rate. Jolly reported a mortality of 61.5 per cent in 26 cases and Allicke, in reviewing 83 cases from the Turkish and Italian campaigns, found a mortality rate of 48 per cent. Inasmuch as recent reports of abdominal or wounds have shown a considerable decrease in mortality from the results of World War I and thoracic injuries in the present war have not been fatal as often as formerly, the author believes that thoraco-

SURGERY OF THE ABDOMEN

abdominal injuries should likewise show a reduction in mortality rate.

A true thoracoabdominal injury signifies that the missile has traversed both the pleural and peritoneal spaces and has penetrated the diaphragm. The author believes that if separate missiles have entered each of the cavities and the diaphragm is intact, the condition should be termed a combined thoracic and abdominal injury.

In a 10 month period during the Italian campaign in 1943 and 1944 31 thoracoabdominal injuries were treated by a thoracic surgical team in a field hospital. The patients had been seriously wounded and could not safely be evacuated. Of the 31 patients, 19 were operated on with 6 deaths a mortality of 30.7 per cent. Two were not operated upon. Of these, one was transferred to another installation. The second patient had a left thoracoabdominal injury a right traumatic thoracotomy traumatic amputation of the right arm and a serious right thigh wound. In spite of 3500 c.c. of blood and 500 c.c. of plasma, the blood pressure never was attained and the patient died 5 hours after injury without coming to surgery.

In 10 cases the lesion was on the right side and in 18 cases, on the left side. One case was bilateral, the same missile having traversed the abdomen and both pleural cavities. In the 10 right sided cases the liver was injured in every instance and was practically the only organ involved. The right kidney and adrenal were each injured once. Of the 18 left sided cases the spleen was injured in 10, the stomach in 8, the pancreas colon in 8, the liver in 7, the jejunum in 4, the pancreas in 2 and the adrenal in 1 case. In the patient with bilateral injury the liver was the only abdominal organ involved.

In 22 patients the injuries were produced by fragments of high explosive shells or bombs and in 7 by bullets.

The authors state that sufficient evidence of thoracoabdominal injury to indicate operative interference is in most instances unmistakable. Thoracic involvement is usually apparent—a through and through wound of the costal cage or roentgenographic evidence of an intrathoracic foreign body. Abdominal injury by a missile whose site of entrance is thoracic may be more difficult to determine. Penetrating chest wounds may leave doubt as to the presence or absence of peritoneal perforation. Penetrating missiles must be located by posteroanterior and lateral x rays.

In questionable cases, physical signs are of little aid. Abdominal pain and rigidity are so often present in thoracic cases that injury to a hollow viscus has not occurred but occasionally it is present in patients with abdominal injury confined to the liver or spleen, or the large bowel. Pneumothorax and pneumoperitoneum as diagnostic aids are not practical for the acute phase.

It is just as necessary to explore any doubtful thoracoabdominal injury as it is every questionable

abdominal penetration. Even if no hollow viscus is penetrated a damaged spleen may be fatal or an overlooked perforation of the liver may cause a bile erysipema. Any missile larger than 3 mm. in the liver may produce enough damage to warrant exploration.

The choice of surgical approach depends on three factors (1) whether more extensive damage is expected in the chest or in the abdomen (2) whether the damage can be repaired easier from above or below and (3) the personal choice of the physician which is dependent upon his training and experience.

The advantages of the transthoracic approach are (1) if there is much thoracic damage as well as abdominal damage the thoracic part cannot be done from below (2) certain upper abdominal lesions are more easily handled through the diaphragm (3) the diaphragmatic repair is best accomplished through a thoracically (4) it permits exteriorization of the colon through a subcostal gridiron incision than if a greater distance from the operative incision than if a celiotomy is done (5) postoperative pain is less severe from a thoracotomy than from a celiotomy (6) the patient can be carried in light anesthesia (7) although abdominal relaxation is not necessary (7) although not apparent at first, considerable damage to the intrathoracic organs may be present.

Two factors favor the abdominal approach (1) it is indicated to repair lesions of the lower ileum, cecum ascending lower descending sigmoid and hepatic flexure of the colon and (2) if the thoracic disturbance is minimal and operative interference is not indicated abdominal exploration prevents entering another serous cavity.

Certain lesions are best done from above and others from below. The author believes that all questionable cases should be done from above, and that one should not hesitate to do both a celiotomy and thoracotomy. He opposes division of the costal cage to extend a thoracotomy incision on to the abdomen as it makes an unstable chest and increases the chance of postoperative pneumonia.

It is important to secure an airtight closure and stable thoracic cage complete and rapid re-expansion of the injured lung and maintenance of a clear tracheobronchial passage during the postoperative period. If a surgeon cannot accomplish these objectives he should use the abdominal approach.

A skilled anesthetist is a must for thoracocelotomies and the use of an endotracheal gas-oxygen ether closed system is the author's choice.

For a thoracotomy incision the author uses the eighth to the tenth rib depending on the exposure desired.

Careful closure of the diaphragm is essential and the author suggests a two-layer incision with interrupted cotton or silk sutures.

Temporary paralysis of the phrenic nerve by serving enhances healing and the author has observed no untoward pulmonary complications attributable to the diaphragmatic paralysis.

Liver lesions should be packed and drained subcostally in such a manner as to provide dependent

drainage. Failure to do this may lead to bile peritonitis.

Closure of the chest and lung re-expansion are of basic importance in a transthoracic procedure and the author discusses his method of chest closure. In some cases the chest is drained under water usually by 2 catheters one anteriorly and one posteriorly in the second interspace. If not drained the patient must be frequently examined and any accumulation of air or fluid must be aspirated. In the present series the average number of aspirations in drained cases was 2.3 while in the undrained cases it was 0.8. The author does not drain except in unusual cases, and he has found that complete early lung expansion is more often achieved without drainage.

There are 3 important points in regard to the postoperative care of the thoracic phase of thoracoabdominal injuries. The first is removal of air and fluid in the chest until complete lung expansion is achieved. The second problem is that of the removal of bronchial secretions, in many by bronchoscopy at the completion of operation. This was done in 13 of the 29 cases. In the ward signs of excessive bronchial secretion should be combated by supporting the patient's chest to make coughing more effectual. If this is not effective tracheal aspiration by catheter is tried and as a last resort, bronchoscopy. So important is this postoperative treatment that the author feels all members of the thoracic surgical team should be competent bronchoscopists. The third factor is the control of postoperative pain which should not be severe in a thoracocelotomy when the intercostal nerves have been paralyzed. Pain is better controlled by paravertebral intercostal nerve block than by resorting to morphine.

Of the 6 fatal cases 2 patients died of uremia on the third postoperative day. At necropsy this patient had a large infarct of the kidney. One patient died during bronchoscopy after operation probably of "vagal reflex" 1 died on the second postoperative day of a fulminating pneumonia another died of strangulation on the ward the fifth patient died of

uremia on the third postoperative day. The last fatality in a patient with a right pneumothorax, a left thoracoabdominal injury a spleen injury and transection of the jejunum and colon, occurred on the operating table. The patient was in severe shock with gross contamination of the pleural and peritoneal cavities, and failed to survive the operation even with adequate blood replacement.

The average time-lag from injury to operation was 8 hours for the fatal group and 11.4 hours for the nonfatal group which would indicate that probably the more severely wounded died before reaching any roedical installation.

Three of 8 patients with colon injuries died (37.5%) but in only 1 patient was this the primary cause of death. Five of the 18 patients with left-sided lesions (27.8%) died as compared with the figure of 0.1 per cent for the death of the 9 with right-sided lesions. These figures mirror the increased seriousness of left-sided lesions.

The death rate increases with the number of abdominal organs injured. One death in 13 (6.6%) occurred in this series when one viscous was injured, while 5 deaths in 14 (35.7%) occurred when 2 or more abdominal organs were injured.

From these cases the author draws the following conclusions:

1. An expert physician anesthetist experienced in administering intratracheal anesthesia is invaluable for the proper function of a surgical team treating thoracoabdominal injuries.

2. Fatalities rarely occur on the operating table. They are usually the result of postoperative pulmonary complications necessitating tracheal or bronchial aspiration by catheter or bronchoscopy.

3. Pulmonary re-expansion after a thoracic operation is of utmost importance and must be pursued vigorously until the end is attained.

4. Prolongation of the time interval from injury to operation is not as significant in respect to mortality as are the factors of proper anesthesia and postoperative care.

ROBERT R. BUCKLOW M.D.

GYNECOLOGY

UTERUS

McLennan, G. E.: Results of Various Types of Treatment in Adenocarcinoma of the Endometrium. *Am J Obst* 1945 50 354.

The results of treatment in the University of Minnesota Hospital of 225 patients with adenocarcinoma of the uterine corpus have been reviewed. One hundred and eleven of these were seen more than five years ago. No patient has been lost in the follow-up program.

The absolute 5 year cure rate has been 45 per cent including certain patients previously treated elsewhere. The exclusion of the latter patients does not improve the end results.

Poor results are shown to follow the routine use of radium and x ray alone. Certain patients so treated may be salvaged even many years later by hysterectomy for recurrent or persistent carcinoma. Good results have followed the use of total hysterectomy with or without preoperative or postoperative irradiation.

Since the beginning of 1939, only 53 per cent of the patients have been able to go through a planned standardized routine of treatment. The reasons which necessitated modifying the standard therapy are shown in detail. Approximately 70 per cent of the patients were given what might be termed adequate treatment, in the sense that total hysterectomy was performed.

In the past 5 years only 1 patient of the group receiving routine or standardized treatment has died of recurrent carcinoma.

The operative mortality for the entire series has been 5.8 per cent, or 3 per cent, corrected. The results in terms of immediate morbidity and mortality in 38 patients who were given full tolerance doses of deep x ray preceding intrauterine administration of radium and hysterectomy were undesirable. It is suggested that preoperative deep x ray therapy will add nothing to the ultimate cure rates.

No conclusions can as yet be drawn from recent experience with the intrauterine administration of radium and total hysterectomy in 4 to 6 weeks.

The final results in the treatment of carcinoma of the uterine corpus are predetermined to a considerable extent by the nature of the metastases medical and surgical complications age, weight and nutritional status.

EDWARD L. CORRELL, M.D.

ADNEAL AND PERIUTERINE CONDITIONS

Brayfogle, H. S.: Death from Air Embolism following Insufflation. *J Am Med Ass* 1945 129 342

The author reports the fourth case of air embolism resulting from vaginal insufflation during pregnancy

Previously 1 case from Canada and 2 cases from England have been reported in the literature.

In the present case 1 per cent of silver picrate in kaolin was insufflated with a Shelanski insufflator into the vagina of a woman who had been pregnant for a period of seven months. In 5 minutes the patient developed pallor, dyspnea, cyanosis, and sudden collapse. Twenty minutes following the onset of the symptoms the patient died.

Postmortem examination revealed gas bubbles in the right auricle and ventricle of the heart, edema and congestion of the lungs with an infarct in the left lower lobe of the left lung.

It is supposed that air entered the systemic venous circulation at the site of the placental implantation and was carried directly to the right cardiac auricle.

Some experimental work was carried out and it has been estimated that under positive pressure 500 c.c. or more of air was injected into the pregnant uterus within a brief interval, thus producing the fatal air embolism.

CATHERINE B. HERS, M.D.

MISCELLANEOUS

Clayton, S. G.: Carcinoma of the Female Urethra (Review of the Literature and Report of 3 Cases). *J Obst Gyn Brit Empire* 1945 52 508

Urethral carcinoma appears to be more common in the female than in the male. Nichol stated that 149 cases had been reported in males and 262 cases in females. Hamann and Goebel found that it accounted for 0.16 per cent of gynecological carcinomas, but Menville found only 1 instance among 43,000 gynecological cases.

Urethral carcinoma is usually a disease of the postmenopausal woman the average age in 109 cases being 53 years.

The disease is mostly seen in parous women, and following Ehtendorfer most authors have mentioned trauma or chronic inflammatory processes as etiological factors. Urethral carcinoma is sometimes suspected to be a predisposing lesion but in view of the frequency of occurrence of carcinoma, it is hard to be sure that the supposed relation is not merely that of chance.

Whitehouse divided the cases into urethral and vulvourethral types, and the latter are found about twice as often as the former. Whitehouse's account of the gross pathology is still one of the most valuable and it is difficult to add much to his description.

Urethral carcinoma. This is seen in two common forms: (1) in the usual form the growth appears as a malignant ulcer in the urethral floor most often in the distal urethra, and (2) the less common form is that of perirethral induration extending for some length along the urethra with late ulceration.

Vulvourethral carcinoma. This occurs in 3 forms: (1) a vascular papillomatous nodule at the posterior

margin of the urethral orifice (2) a nodule that breaks down to an ulcer in the vestibule and (3) a scirrhous induration around the urethral orifice.

On microscopic examination the neoplasms are found to be of various types: squamous cell carcinoma, columnar cell carcinoma (both simple and adenocarcinoma), mucoid carcinoma and undifferentiated types. In most of the series the squamous cell carcinoma predominates.

Menville has stressed the similarity of the growths to neoplasms of the bladder.

Urethral carcinoma does not produce much discomfort in the early stages and even after severe symptoms appear there is often so much delay before advice is sought that extension to the bladder, vagina or lymph nodes may have already occurred when the patient is seen.

Perhaps the most common of the early symptoms is painful micturition. Difficult micturition or retention may occur in other cases, frequency. Bleeding is a common symptom more especially with micturition. Local tenderness and dyspareunia also occur with the more superficial growths. Some of the patients may report a swelling in the region of the urethra.

On examination the growth may be seen projecting from the urethral orifice or in other cases it may be felt *per vaginam* as a line of induration along the urethra. Enlarged inguinal glands are found in about 20 per cent of the cases at the first examin-

ation. Biopsy is the final and essential step in diagnosis.

As regards the primary tumor, the choice between surgical excision and irradiation is obviously affected by the position and extent of the growth. If the posterior urethra is involved the growth can be excised only at the cost of permanent incontinence. Irradiation has less operative risk, although there is a possibility of both fistula formation and stenosis. The radiosensitivity of the growth varies with its type and although it is generally stated that the squamous cell types are sensitive there is less agreement about the columnar cell types.

As regards the inguinal glands, there is the same choice between surgical excision and irradiation, and also there is fairly general agreement that surgery offers the best results. The nodes are often infected, and the overlying skin may not tolerate the large doses of radiation necessary to reach the glands in their fatty bed.

The results in general are disappointing. Spauld and Parsons, for example, found only 15 survivors among 110 patients after 3 years. Tanning reported 14 cases, and in 2 of these the disease was too advanced for treatment. Of the 12 patients treated, 8 were subjected to irradiation, with only 1 survival, and 3 were treated by excision of the primary growth with Bassett gland dissection; all 3 survived.

Three cases are reported.

DANIEL G. MORTON, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Greene, G. G.: Abdominal Pregnancy; 3 Cases Near or Past Term and 1 Case of Early Abdominal Pregnancy. *South M. J.*, 1945 38 74

In abdominal pregnancy the problem of delivering the fetus is usually simple but that of delivering the placenta requires a difficult decision. There are three methods of approach namely (1) marsupialization of the placenta (2) removal of the placenta and (3) leaving the placenta in place. The first has been discarded by most experienced obstetricians of today because of the greater risk of infection in a wound which may be open for many weeks. Removal of the placenta places both the patient and the operator in a dangerous position. On first inspection of the placental attachments one may think that the placenta can be removed with ease, and find, too late that there is an unsuspected attachment which involves a vital area. Such meddling surgery may cost the life of a patient who could have been spared.

The 3 cases of advanced abdominal pregnancy presented bring out what seems the most desirable method of caring for the placenta. In these the cord was cut short and tied. As much of the membrane as could be removed was cut away. The placenta was left intact and the abdomen closed tightly with out drains. Complications may arise and it may even be necessary to do a second operation for removal of the placenta, but this can be done with greater security later as the placenta will be in a degenerative stage and possibly detached and lying free in the abdominal cavity. Occasionally suppuration may occur but this can be taken care of by simple drainage.

Since hemorrhage is a primary consideration whatever the approach the patient should be thoroughly fortified against it prior to operation. Anspach and others have agreed that the optimum time for operation is from 6 to 8 weeks after the fetus is known to have expired. This, of course is desirable if the placenta is to be removed but does not seem necessary in most instances. The placenta will be absorbed by the body if the "hands off" policy is followed.

Abdominal pregnancy can be diagnosed with less difficulty if one suspects it in any case which does not seem just right.

X-rays are very valuable when used in advanced abdominal pregnancy especially when a diagonal or other peculiar position of the fetus is noted.

Alertness of the obstetrician and early diagnosis may save more infants. DANIEL G. MORTON, M.D.

Greene G. G.: A 7 Year Review of Eclampsia with Special Reference to Treatment with Veratrum Viride. *Am. J. Obs.*, 1945 50 427

Of the 150 patients in this review 104 were primigravidae. This group of cases revealed that true

eclampsia is far more frequent in the women in whom chronic kidney damage has been present for some time. Veratrum viride is not of much value. In more than half of the patients the eclampsia began in the antepartum period.

During these 7 years every method of treatment known seemed to have been given a chance at one time or another.

In the year 1937 many cesarean sections were done. It was in this year that the mortality reached its highest peak. Nine sections were done in 20 cases (45 per cent) that year. Seven of the 9 patients expired. Five of the 7 were treated in the hospital for only 24 hours or less before operation was performed. All of these expired. This emphasizes the urgent need for control of the eclampsia before any operative measure is attempted.

Fifteen cases were seen from 1941 to 1942 inclusive. Fourteen of these received veratrum viride. All of the patients recovered. The patients are treated without giving them any morphine or barbiturates. Paraldehyde per rectum is the choice method of anesthesia. It was found that after treatment had been started 50 per cent or more of the patients did not continue to have convulsions or at most they had only 2 convulsions and in a short period of time they were rational and responding to questions.

No attempt at delivery should be made until the convulsions have been controlled and the patient is rational for one or two days. A number of these cases will go into labor spontaneously during this period if not the induction of labor can be accomplished by the simpler methods, with drugs or some minor operation such as rupturing of the membranes. A very small number of cases may not respond to any of these. If the patient is a primipara near term with a closed thick cervix cesarean section can be considered and performed rather safely provided the eclamptic state has been controlled for a time but the patient is beginning to show evidence of returning to her former condition by a rise in blood pressure, an increase in albumin, and casts in the urine. The author does not like to use bag in ductions in primiparas for this or any other reason.

Eclampsia is a complication of pregnancy prevalent mostly among the young negro women in the South as the result of improper prenatal care.

EDWARD L. CORNELL, M.D.

Moscafee, C. G. H.: Placenta Previa. A Study of 174 Cases. *J. Obs. Gyn. Brit. Empire* 1945 52 313

Since 1937 all cases of antepartum bleeding admitted to the Belfast Royal Maternity Hospital have been treated under the direct supervision of the author. In this article he reports the results of the treatment of 174 cases of placenta previa which were classified as to location as follows: Type I (low-lying)

TABLE I METHODS OF DELIVERY

	No. of cases	Still-births or Deaths	Per cent
Artificial rupture of membranes	33	7	3.4
A. R. M. and Willett's forceps	9	9	47.4
Vernon	3	17	77.3
Cesarean section	68	2	1.9
Breech	6	5	83.3
None	7		14.3

50 Type II (marginal), 37 Type III (partial) 46 and Type IV (complete) 41

The physician who first sees a patient with placenta previa is responsible for getting her to a hospital where suitable treatment can be administered. The type of placental implantation can be determined and the program for treatment outlined only after careful vaginal examination. The time when the vaginal examination is made, however is of utmost importance to the final outcome for the baby. Since many cases of placenta previa manifest themselves early in the last trimester of pregnancy and since most of the infant deaths are due to prematurity delay in treatment to allow the baby to grow should increase the survival rate. The author contends that severe hemorrhage particularly in primigravidae, and further separation of the placenta usually follows vaginal examination, and cites several cases of "silent" previas discovered at cesarean section for other conditions. The small hemorrhages which may occur from time to time in the unexamined patient are of little consequence.

If the initial bleeding occurs near term no time should be lost in initiating treatment but several patients were observed from 1 to 14 weeks before being examined. The average birth weight of the infants in the first 47 cases delivered at the time of the first bleeding was 5 pounds 3 ounces with a fetal mortality of 47 per cent, and in the last 47 cases observed and examined later 6 pounds 13 ounces with a mortality of 6 per cent. The total fetal mortality rate was 53.5 per cent, as compared to 51.3 per cent for the previous 4 years.

The author states that the site of the insertion of the umbilical cord into the placenta is of importance in fetal survival. If the cord is inserted low the baby is likely to die, whereas it usually will survive if the cord is attached high, on the portion of the placenta which remains adherent to the uterine wall.

The methods of delivery with the associated fetal mortality are outlined in Table I. The lower segment cesarean section is preferred, but care should be taken that the placenta is located before the uterine incision is made so that it is not incised.

J. ROBERT WILSON, M.D.

Vartan, C. K.: The Behavior of the Fetus in Utero, with Special Reference to the Incidence of Breech Presentation at Term. *J. Obst. Gyn. Brit. Empire*, 1945 52: 47

Studies show that spontaneous cephalic version from a breech presentation normally occurs during

pregnancy. It was formerly thought that breech presentation occurred most commonly when there was a decrease in size of the pelvic cavity but observation of the cases shows that the factors which prevent spontaneous version are the real etiological factors which persist to term.

Three theories formerly held to explain why cephalic rather than breech presentation occurs are contradicted:

1. The statement that the smaller circumference of the breech at term causes it to present in a small pelvis rather than the head is refuted by the observation that presentation is decided long before the fetus attempts to enter the pelvic brim.

2. The theory that the smaller circumference of the fetus adapts itself to the small end of the uterus is refuted by the observation that the uterus at term is not pyriform especially in the multigravida or in hydramnios.

3. The argument that gravity causes the head to present rather than the lighter breech is refuted by the observation that breech presentation is much more common early in pregnancy than later and that the woman's upright position is not constantly maintained.

One thousand cases of breech presentation occurring during some period of pregnancy were observed in a series of 3,875 patients. Breech presentation is regarded as a common occurrence up to the thirty-fourth week of pregnancy, with spontaneous cephalic version between the thirty-first and thirty-third weeks in most cases. In this series spontaneous cephalic version occurred in 680 of 1,000 cases. The incidence of parity on spontaneous version is unimportant; in this series the incidence was equal in primiparas and multiparas. Reversion seldom follows spontaneous version; it occurred in this series in only 15 women, most of them primiparas, of which 3 underwent a second spontaneous version. External version has a higher reversion rate than spontaneous version; of 330 cases in which external version was done 52 per cent (77 cases) had a reversion to breech presentation. Other observers have arrived at figures of 33.3 and 51 per cent. External versions performed after the thirty-third week show a lesser tendency to reversion than those done earlier; among 22 per cent of failed versions in this series, 36 cases presented by the breech at birth, 38 had spontaneous reversion and 13 were reverted by the obstetrician. The majority of persistent breech presentations show an extended attitude at term; a small proportion show very little liquor (in this series 3%); most of them occur in primiparas (31 in this series).

Spontaneous podalic version occurs occasionally; it was observed in 134 cases (3.4% of the total of 3,875) and in 45 of these it occurred as an initial movement, one-fourth of the cases readjusting themselves. No organic or other factor was suggested as influencing spontaneous podalic version. External podalic version was performed in 2 cases of the total of 85 breech presentations at birth. In 1 of the 31 unheralded breech deliveries the infant was stillborn.

Patients should be informed that the breech presentation is normal at a certain stage in the pregnancy furthermore it should be realized that spontaneous version occurs in 3 out of 5 patients. The cause of spontaneous version is not as easy to explain as the cause of its nonoccurrence. It apparently happens that spontaneous version does not occur (1) when the fetus is abnormal or premature, (2) when there is little liquor (3) when the limbs are extended and (4) when twin fetuses mutually prevent each other from turning.

In performing external version one must induce the fetus to undo its extension and then to turn it rather than to attempt to force around an inanimate object of the wrong shape. Gentle cephalic pressure will induce vigorous movements and often undo the extended attitude. Gentle pressure on the facial aspect and backward turning is often successful when forward version fails and may be repeated weekly or oftener. Anesthesia is inadvisable and unlikely to help in most cases. Accidental hemorrhage at the time of version is very rare. The incidence of death because of dystocia in breech delivery is no higher than in the case of vertex delivery. The mortality rises when a difficult delivery is added to a breech presentation, and no woman with a large baby in persistent breech presentation in the extended attitude should be allowed to deliver herself.

Skagrams have been most valuable in breech cases for determining the fetal attitude and the amount of liquor and therefore have aided in the subsequent management of the case whether it be induction of premature labor or caesarean section at term.

PURLEY B. CRASE, M.D.

O'Driscoll, D. T.: Acute Hydramnios. A Brief Survey of the Recent Literature, with the Report of a Case Simulating Concealed Accidental Hemorrhage. *J. Obst. Gyn. Brit. Empire* 1945 52: 496.

Acute hydramnios has been reported 90 times in the literature. The cause is still unknown. The amniotic fluid is generally regarded as of dual origin. On the maternal side the fluid comes from the blood plasma and is probably changed by its passage across the placenta and amnion. The amnion is capable of true secretory activity. The fetus probably contributes by urinary secretion and by transudation from the fetal surface and umbilical cord. Under normal conditions the fetus also probably helps to regulate the amount by its constant swallowing of liquor with the subsequent passage of excess fluid into the fetal circulation and across the placenta into the maternal blood stream.

In hydramnios therefore, pathological conditions both on the maternal and on the fetal side may be etiologic factors.

Analysis of the last 40 cases of acute hydramnios that appeared in the literature revealed the following associated conditions: 8 cases with twins, 7 cases with anencephalus, 2 cases with teratoma of the

neck, 1 case each with multiple deformities, atresia of the esophagus, congenital adenoma of the lung and hydrocephalic anophthalmic monster. The conditions present in the mothers were ascariasis appearing acutely in puerperium, diabetes mellitus and eclampsia.

In this article, the author reports 1 case of acute hydramnios simulating concealed accidental hemorrhage. The patient was delivered of a stillborn anencephalic fetus.

The case is of particular interest because the patient presented a typical picture of concealed accidental hemorrhage. Not until the membranes were artificially ruptured and the amniotic fluid was forcefully extruded was the diagnosis made. The symptoms were sudden severe abdominal pain with vomiting. On admission to the hospital the patient looked pale and shocked. The abdomen was extremely tense hard and tender, occasional painless contractions were palpable. Rectal examination revealed the cervix to be closed. The uterus reached to two fingers below the xiphoid.

The main points in the differential diagnosis between acute hydramnios and concealed accidental hemorrhage are: (1) the duration of the symptoms, with a slower onset in hydramnios; (2) abdominal enlargement, greater in hydramnios; (3) ballottement will favor a diagnosis of hydramnios; (4) in investigation of the previous history; (5) abdominal puncture of the uterus by a fine needle (Courtois).

Other conditions requiring differentiation are ovarian cysts, ascites and multiple pregnancy.

The treatment of acute hydramnios is usually conservative. If the fetus is normal, an effort is made to carry the pregnancy to term. This can be done occasionally by frequent decompression of the uterus by the technique of Courtois. If the pregnancy is at term or the fetus is deformed, labor may be induced.

Drainage of the fluid, either through the abdomen with a needle or by rupture of the hind waters with a Drew Smythe catheter, is recommended by the author as a desirable method of inducing labor.

The author concluded that acute hydramnios occurs in patients who would develop hydramnios in any case but because of the introduction of an additional factor the symptoms arise acutely. The additional factor is a uterine musculature that is oversensitive to undue stretching caused by the presence of an extra amniotic sac or trauma.

HARRY FIELDS, M.D.

Burch A. E.: The Association of Erythroblastosis Fetalis and Accidental Antepartum Hemorrhage. *J. Obst. Gyn. Brit. Empire* 1945 52: 495.

It is concluded from the evidence in two series of cases that Rh negative women are abnormally prone to have accidental antepartum hemorrhages. It is also postulated from the series that the ensuing placental damage may be the factor which produces erythroblastosis in the offspring by allowing the transplacental passage of antigen and agglutigen. In 2 of 3 cases of erythroblastosis fetalis in the Queen

Charlotte Hospital series reported there was an associated premature placental separation and ante partum hemorrhage the association of two such rare conditions seemed significant although the number of cases was small.

Among the 10 cases of accidental antepartum hemorrhage reported from St. Ulge's Hospital 5 of the women were Rh negative and had Rh positive husbands and 3 had anti Rh agglutinins. Three of these women had a hemorrhage just prior to delivery and 1 of them had a jaundiced baby. 1 gave birth to a child with gross hydrops, and the third had a stillbirth. Two of the women had a hemorrhage some weeks before delivery and both had stillbirths. In all but 1 of the cases there was an association between (1) the time between delivery and bleeding, (2) the severity of the erythroblastosis and (3) the titer of the agglutinins. This suggests possibly the advisability of an early induction of labor when agglutinins are present in the mother in order (1) to prevent hemorrhage in the mother or (2) to prevent erythroblastosis in the infant, but this must be balanced against the risk of prematurity.

The importance of the Rh testing of mothers is stressed especially because Rh negative mothers are prone to have hemorrhages on account of their immunization and run the risk of incompatible transfusions.

In explaining the disproportionately low incidence of erythroblastosis in the offspring of even Rh negative women authorities are quoted as stating that (1) many marriages are childless or produce only 1 child (2) there is a variable potency of the Rh antigen in the infant which produces agglutinins in the maternal blood (3) there is a variable ability of the placenta to prevent the passage of the antigen (4) there is variable maternal response to the introduction of the Rh antigen into the blood stream and (5) there is a variable ability of the placenta to prevent the passage of the agglutinins.

PHILIP B. CHASE, M.D.

Soloway H. M.: Control of Syphilis in Pregnant Women. *J Am Med Ass* 1945, 129: 500

The Illinois Department of Public Health has reported the results of its plan for the prevention of congenital syphilis.

The plan calls for a blood specimen from every pregnant woman to be sent to an approved laboratory for serologic examination. The report is sent to a central agency which contacts the family physician. Information in regard to treatment as well as the necessary drugs are provided if so desired. In addition, every facility to assure adequate treatment and follow-up is provided for the physician.

Adequate information was available in 1,445 cases. In the remaining 243 it was considered inadequate for a variety of reasons.

The most significant finding was the relationship of the outcome to the onset of treatment. When treatment was started before the end of the fourth month the total fetal loss was 6 per cent. Treatment

delayed until the fifth month yielded a fetal loss of 17 per cent. Beyond that time the fetal loss reached 49 per cent and in the absence of treatment it increased to 73 per cent.

Reactions to antisyphilitic treatment seemed insignificant. There were no fatalities, although 25 serious reactions were reported.

This report stresses the well known fact that congenital syphilis can be prevented by early diagnosis and adequate treatment. In prevention of congenital syphilis the emphasis should be placed on early detection. This can be accomplished if the patients are educated to seek early prenatal care and if the physician does a routine serologic test. Once the disease is diagnosed every effort must be made to carry out adequate treatment and follow-up studies on both the mother and child.

JAMES F. DONOVAN, M.D.

Hudson G. S. and Rucker M. P.: Spontaneous Abortions. *J Am Med Ass* 1945, 79: 512.

Statistics on the frequency of spontaneous abortion vary widely. This study covers 1,000 consecutive obstetrical cases in which there were 108 abortions of all types. When the 25 therapeutic and 2 criminal abortions were subtracted there remained 94 spontaneous abortions, an incidence of 9.4 per cent.

The incidence was then noted in relation to certain factors and compared to the anticipated incidence of spontaneous abortion.

In patients who had had previous children or abortions, the incidence was higher. An increase was noted also in obesity, pelvic inflammatory disease, retrodisplacement, fibroids, hypothyroidism, diabetes, in women who used tobacco and in those who gave a history of previous sterility. The increase was particularly prominent in the last two mentioned instances.

Factors which the authors stated had no effect on the incidence were the marital status, syphilis, acute upper respiratory infections, and falls.

JAMES F. DONOVAN, M.D.

LABOR AND ITS COMPLICATIONS

Mandel, H. S., Graff S. and Graff A. M.: Placental Senescence and the Onset of Labor. *Am J Obst* 1945, 50: 47

Estimation of the nucleocytoplasmic ratio reveals that the placenta ages in a uniform and continuous manner from approximately 8.6 per cent at 2 months to 3.6 per cent at term. The growth of the placenta conforms to theoretical and statistical laws of growth. The toxemias of pregnancy have no effect upon the placental age as measured by the nucleocytoplasmic ratio. Death of the fetus in utero lowers this ratio. I.e., causes increased aging, probably by some ant lytic process.

There is no correlation between placental senescence and the onset of labor.

EDWARD L. COW, M.D.

PUERPERIUM AND ITS COMPLICATIONS

Fulton A. A.: Vitamin C and Lactational Mastitis.
Brit. M. J. 1945 1 458

Of 2 Scottish clinics for pregnant women designed by the author as clinic A and clinic B respectively each served about half of the town, and there was no distinction among the patients received as to social status or other condition. The group of patients attending clinic A who received ascorbic acid is referred to as group A and consisted of 124 women. The patients attending clinic B did not receive ascorbic acid being the controls this group is referred to as group B and consisted of 126 women.

In group A each expectant mother was given 50 mgm. tablets of ascorbic acid daily at about 3 months before the onset of labor and until about 6 months following childbirth. On admission to the Maternity Hospital all of the patients in both groups were given the saturation test for vitamin C as devised by Harris and Abbaay (*Brit. M. J.* 1937 2 1426). The patients in group A required an average of only 1 673 mgm. and those in group B 3 076 mgm. for saturation yet approximately the same percentage (25%) developed mastitis although the former were more favorably situated as regards the two factors considered to be predisposing causes of mastitis in lactating women primiparity (in from 47.6 to 52.4%) and delivery in the hospital (15 women of group A were delivered at home).

From these results it would appear that vitamin C administration per se has no influence in reducing the incidence of mastitis.

The subsequent tests on the patients with mastitis after the saturated state had presumably subsided from the first saturation tests (in about 3 weeks) showed that (as in the first test) on the average of 1,410 mgm. of ascorbic acid were required to saturate the patients of group A and 3 117 mgm. were required to saturate the patients of group B. The saturation test according to the standard of the League of Nations showed that 63.7 per cent of the cases of group A reached the saturation stage within

2 days of the beginning of the test period whereas all of those in group B reached this state but at a much later date.

The patients in group B were even in a somewhat better condition with regard to the severity of the mastitis because the process subsided without suppuration in 9 of the women in group B but in only 3 of those in group A.

The author admits however that there are a number of vitiating factors at work in this study the most important being perhaps the fact that no account was taken of the possible effects of other food deficiencies in these patients and also the fact that the vitamin C administered was synthetic whereas it is possible that the maximum benefit may be obtained only when it is given in the form of natural foods.

JOHN W. BRENNAN, M.D.

NEWBORN

Gamble, T. O., Miller, L. C., and Tainter, M. L.: Benzyl Penicillin; Clinical Toxicity and Efficacy by Mouth in Impetigo in the Newborn Infant. *Am. J. Obst.* 1945 50 514

The benzyl ester of penicillin given by mouth quickly cleared 16 attacks of impetigo contagiosa in 15 infants in a maternity hospital and terminated a protracted epidemic.

This new form of penicillin is stable at room temperature and can be supplied to the physician ready for use. It is as effective by mouth in impetigo as is the sodium penicillin administered by injection. The great advantage of being able to give benzyl penicillin orally marks a major advance over the previous injection therapy in managing this difficult condition. The new therapy avoids staining the skin and linen as in the treatment with dyes and also does not require the painful surgical removal of crust as in the local therapy of impetigo.

The effectiveness of benzyl penicillin demonstrated in this study points out the need for extensive tests of this preparation in other types of infection.

EDWARD L. CORNELL, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Huff, F. M., and Boger W. P., Jr: Renal Hypoplasia with Hydroureter and Primary Amenorrhea. *J Urol. Balt.*, 1945 54: 6.

The frequent coincidence of genital and upper urinary tract anomalies has been noted and reports of many cases have emphasized this combination of abnormalities.

The case here presented is of interest by reason of left renal hypoplasia, a greatly dilated and tortuous ureter with a stricture of its intramural portion, aberrant vessels crossing the lower ureter and primary amenorrhea, assumed to be due to congenitally defective internal genitalia.

While renal hypoplasia is not uncommon, the great ureteral dilatation found with it in this instance is unusual. The futility of endocrine therapy in this case strongly suggested an end organ structurally incapable of response. From this experience it would appear that the complaint of primary amenorrhea justifies investigation of the urinary tract.

JOHN E. KIRKPATRICK, M.D.

Newman H. R.: Renal Disease in AAF Regional Station Hospital. *J Urol. Balt.*, 1945 54: 126.

The incidence of renal disease is considered to be at the lowest figure during the draft age of from 8 to 38 years.

The present study includes 17 cases of renal lesions in patients between the ages of 18 and 38 years. This study reveals the large number of cases of renal disease which may be encountered in an average sized station hospital (approximately 500 beds) over a period of 12 months. In this period of time there were approximately 475 urological admissions, and about 1,500 patients were seen as out patients. Patients with venereal disease were not included on this service.

The renal lesions most often encountered were congenital anomalies, infections, and calculi on the other hand nephropathosis, albuminuria, hematuria of unknown origin, nephritis, and tuberculosis were found to be relatively uncommon.

JOHN E. KIRKPATRICK, M.D.

Nesbit, R. M., Keltner, W. A., and Lynn, J. M.: The Prognosis of Renal Tuberculosis Treated by Nephrectomy and the Outlook of the Patient Who is Considered Unsuitable for Operative Treatment. *J Urol. Balt.*, 1945, 54: 27.

Data are presented on 260 cases of genitourinary tuberculosis which have been followed for a period of 5 years or more. It is pointed out that in this series males were affected more frequently than females, in a ratio of about 2 to 1 and that the urine in about one-third of the cases was secondarily infected by organisms other than the tubercle bacillus. Fifty

and three tenths per cent of the nephrectomized patients are living an average of 11 years after operation, while 81.3 per cent of the patients not operated upon have died in an average of 3 years. The authors were unable to demonstrate that an accompanying genital complication in the male adds to the mortality of renal tuberculosis and they assume that the higher death rate among males is due to the higher mortality of tuberculosis generally in this particular group.

Three facts derived from these figures have proved to be statistically significant.

1. In nephrectomized patients, a lower rate of survival is found in the group in which acid fast bacilli have been demonstrated in the urine from the kidney not operated upon, by guinea pig inoculation, than in those with normal urine on the "sound" side.

2. In tuberculosis of the urinary tract the survival of females is greater than that of males.

3. The mortality rate of genitourinary tuberculosis is adversely influenced by the presence of bone and joint, or pulmonary lesions. JOHN A. LOER, M.D.

Doornmaashkin, R. L.: Cystoscopic Treatment of Stones in the Ureter with Special Reference to Large Calculi, Based on the Study of 1,534 Cases. *J Urol. Balt.*, 1945, 54: 245.

The author presents a series of 1,530 cases of ureteral calculi, situated at all levels of the ureter and renal pelvis, and lists the results obtained by cystoscopic manipulation in 1,533 cases.

The methods of nonoperative treatment of ureteral stones are classified and evaluated by the author as follows:

Indwelling ureteral catheter. This does not produce dilatation of the ureter adequate enough for the passage of large calculi. It is of distinct value, combined with the administration of sulfa drugs, in cases in which renal infection is a complication of urinary blockage, and should be utilized in these cases prior to attempts to dilate the ureter with rubber bags and metallic dilators.

Methods for forcible removal of ureteral calculi. These include the use of metallic hooks, cages, and baskets and are condemned for general use, as they are dangerous in both theory and practice, resulting in serious damage to the ureter in many instances.

Dilatation of the ureter. This is done at or below the level of the calculus to a degree adequate to allow passage of the stone. It was the method of choice in the management of ureteral calculi in this series of cases.

For the purpose of determining the results of intra-ureteral manipulation, the stones were divided into two large groups. A, small calculi, measuring less than 5 mm. in width, and B, large calculi, measuring 5 mm. or more in width.

There were 780 cases in group A. Tabulation of the results shows that excluding 48 cases of spontaneous passage of stone, 41 cases which were lost to observation and 2 cases in which no cystoscopic manipulation was attempted because of the severity of the renal infection and in which nephrectomy was done, there were only 2 of 689 cases treated in which the cystoscopic manipulation failed or that a successful passage of stone followed cystoscopic intervention in 99.7 per cent of these cases. Six cases of complete anuria were observed in this group, 4 cases showing bilateral calculous obstruction and 2 showing anuria of apparently reflex origin.

There were 741 cases in group B. There was spontaneous passage of the stone in 19 cases and 24 cases were lost to observation. Intraurethral manipulation was successful in 484 cases or 85.9 per cent. The principle of providing ample room for the downward passage of the stone at and below its level was followed in this work. This was achieved by dilatation of the lower end of the ureter with the author's metallic bougies, and by using rubber bags at the higher levels. There were no instances of ruptured ureter or mortality resulting from instrumentation. Operative removal after cystoscopic manipulations had failed was necessary in 80 cases or 14.1 per cent.

In 134 cases of group B operation was performed without a preliminary attempt at cystoscopic manipulation for one of the following reasons: the stone being obviously too large, acute infection, advanced chronic infection and hydronephrosis, an emergency (hemorrhage, impending anuria, or ruptured kidney), a large renal calculus requiring operation associated with a stone in the upper ureter on the same side, renal destruction on the opposite side due to a renal calculus associated with a fairly large stone in the lower end of the ureter, bad impaction, and anatomical anomaly of the urinary tract, ureteral stricture, empyema of the ureter following nephrectomy, the association of stone with renal tuberculosis, or the patient's refusal of cystoscopic treatments.

WILLIAM W. SCOTT, M.D.

Lazarus, J. A., and Marks, M. S.: Primary Carcinoma of the Ureter with Special Reference to Hydronephrosis. *J. Urol.*, Balt., 1945, 54, 140.

In 1934, after a careful search of the literature one of the authors was able to collect 68 cases of primary carcinoma of the ureter, including 3 of his own. Since then 115 additional cases have been reported, which indicates an increased alertness on the part of urologists to the possibility of this disease rather than an actual increase in incidence.

Of the total number of tumors 49 per cent were of the nonpapillary type. Malignant neoplasms were situated in the lower segment of the ureter in approximately 50 per cent of the reported cases, and were associated with ectasia of the renal pelvis in 46.4 per cent and of the ureter in 43.7 per cent because of the tendency of these tumors to occlude the lumen of the ureter. The greatest prevalence of this disease oc-

curred in the sixth and seventh decades. Ureteral carcinomas show marked invasive and metastasizing tendencies, particularly to the regional lymph nodes (28.9 per cent), liver (14.9 per cent) and bones (12.8 per cent).

Although pain, hematuria and the presence of an enlarged kidney are supposed to constitute the characteristic triad of symptoms of this disease, it was found that hematuria alone was by far the outstanding symptom, having occurred in 70.5 per cent of the collected cases. A clear cut and persistent filling defect in the ureterogram, especially when associated with ectasia of the segment of the ureter directly above such a defect in the authors' opinion, constitutes the only pathognomonic sign of ureteral tumor.

The chances of demonstrating filling defects in ureterograms would be enhanced if repeated attempts were made to obtain good ureterograms in all cases which (1) disclose an obstruction in the ureter, (2) bleed through the ureteral catheter as a result of manipulation at the site of the obstruction, and (3) fail to disclose a calculus at the site of the obstruction. Failure to recognize the presence of this disease has led urologists to remove hydronephrotic kidneys only to learn later to their great chagrin that the hematuria had recurred and necessitated a second operation for the removal of the tumor bearing segment of ureter.

The procedure of choice in the treatment of this disease is complete extraperitoneal nephroureterectomy. It is recommended that a cuff of vesical wall surrounding the ureteral meatus also be removed in cases in which the tumor is situated low down in the ureter and especially when the ureteral meatus is involved.

A careful review of the literature has further strengthened the authors' belief in the dangers of incomplete urological surveys for so-called minor urological complaints and a detailed history is given of a case in which the patient was perfunctorily treated on and off for 15 years for cystitis without being subjected to a thorough urological survey. It is believed that the lesion which was found could never have progressed to such large proportions had ureteral catheters been passed during one of the episodes of so-called cystitis.

BLADDER, URETHRA, AND PENIS

Lewis, L. G.: The Treatment of Bladder Dysfunction after Neurological Trauma. *J. Urol.*, Balt., 1945, 54, 284.

The author reviews the anatomy and innervation of the bladder and the physiology of micturition. He believes that the increase in bladder tone following presacral neurectomy is due to increased vascularity of the bladder wall.

The following principles are outlined for the urological care of patients following spinal injury:

1. No instrumentation for 24 hours

2. Absolute aseptic catheterization at 24 hours if necessary.

3. The use of a urethral retention catheter if a second catheterization is necessary.

4. The use of intermittent or tidal irrigation of the bladder with acid solutions to prevent incrustation cystitis.

5. Perineal urethrostomy in selected cases.

6. The use of a well placed suprapubic tube when definitely indicated for long or permanent bladder drainage. This is indicated in complete transverse lesions below L-1. Six weeks is about the limit of tolerance of the urethra to catheter drainage.

Close co-operation between the neurosurgeon and the urologist is required in the care of patients following severe cerebrospinal injury.

WILLIAM W. SCOTT, M.D.

GENITAL ORGANS

MacLeod, D.: The Glandular Nodules in Benign Glandular Enlargement of the Prostate: Its Development and Cause. *Bril J Urol* 1945 7 85

The evidence in brief of the sequence of events leading to the development of the glandular nodule in benign glandular enlargement of the prostate is as follows:

1. At any one time during the growth of the prostate there are present groups of tubules at times unrecognizable which arise from the terminations of the primary and subsidiary tubules of the prostate. They may be collective as in the preperimetric region, or individual.

2. With further increase of the glandular tissue in general, a circumscribed resistance to the growing groups is created in due course by the tissues in which they are situated. It is caused indirectly by a passive force applied to the tissues from the periphery of the prostate as a whole and also from that of the preperimetric region.

3. Growth of the groups against that resisting tissue is accompanied by and causes the formation of, circumscribed capsules of fibrous and/or compressed glandular tissue about them: the groups are thus isolated and so form the glandular nodules associated with the benign enlargement of the prostate.

4. Within the limiting capsules growth of the groups may continue: acinous formation and intra-acinous epithelial proliferation are followed by acinous dilatation and rupture.

The direct cause of benign glandular enlargement of the prostate is continuity of the active glandular growth against a passive and circumscribed resistance derived from the periphery of the prostate as a whole and also from that of the preperimetric region.

The glandular nodule in the benign enlarged prostate is evidence of an attempt to limit the size of the gland.

Peripheral resistance to the glandular growth becomes duly effective in the upper parts of the pro-

state first and in the lower parts last, because of the disproportionate increase of growth in the regions and glandular nodules are in point of time and place likewise formed.

The absence of benign enlargement from the upper part of the posterior lobe of the prostate is due to the destruction of its groups of tubules by pressure from the enlarging lobes in front of it: absence from the lower part is caused by lack of adequate peripheral resistance to its growing groups of tubules.

Benign glandular enlargement of the terminal parts of the lateral lobes of the prostate is equally as rare as the same condition in the posterior lobe and is due to lack of adequate peripheral resistance to the growth of the tubules in those parts.

MISCELLANEOUS

Yamauchi, S.: Chyluria; Clinical, Laboratory and Statistical Study of 45 Personal Cases Observed in Hawaii. *J Urol* Balt., 1945 54 511

The clinical, laboratory and pyelographic studies based on 45 personal cases of chyluria are carefully compared and correlated with those of the cases recorded in the literature and a comprehensive picture of chyluria is here presented.

The etiology and pathology have been discussed chiefly on the basis of the author's experiences with his own material, hence they represent his own views. This material has been added as an adjunct to the main material and the analysis of the records, to aid the reader in obtaining a comprehensive picture of the disease.

The individuals suffering from chyluria had all been exposed to filariae during their lifetime, but filariae were never demonstrated in their blood, urine or as in some cases, tissues. The long period from the last possible exposure to the filariae to the onset of chyluria (in many of these cases) the absence of eosinophilia (in the majority) and several other factors indicate that filariae probably predisposes the patient to this condition but it does not actually initiate it. However anyone who has been exposed to this nematode becomes a potential candidate for chyluria anytime, even many years after the exposure. Thus, the incidence of this disease can be expected to rise in regions where filariae is not prevalent, such as the northern United States, when armed forces return from regions where it is endemic.

Urinary stasis has been considered as the exciting cause of chyluria. Fornix rupture caused by urinary stasis results in a lymphaticourinary communication, and chyle appears in the voided urine if the ruptured lymphatic vessels already contain chyle. Except in a few instances minimal pathological changes sufficient to form varices are probably present in the lymphatics without definite obstruction to the large retroperitoneal lymphatic vessel and thoracic duct. Pregnancy, endocervicitis and prostatic hypertrophy so frequently found in this condition become logical concomitant occur-

rences instead of bizarre associations when viewed in this light

Chyluria is characterized by the appearance of chyle per se in the voided urine. The presence of fat granules in a colloidal state, the presence of albumin, erythrocytes and lymphocytes, the pyelographic injection of the renal and perirenal lymphatics frequently associated with fornix rupture and pyelovenous reflux, and the control of the condition by repeated intrapelvic lavages with sclerosing solutions support the surmise that there is a lymphatic urinary fistula at the fornix of the calyces.

The control of chyluria can be accomplished without much difficulty by repeated intrapelvic lavages of silver nitrate solutions through infundibular catheters, but the cause of urinary stasis must be removed and fat must be eliminated from the diet after such lavages. The success of such management depends on the extent to which the predisposing and exciting causes can be eliminated.

JOHN A. LOEF, M.D.

Solomon, S.: The Treatment of Gonococcal Arthritis with Sulfonamides and Artificially Induced Fever. *Am J Syph.*, 1945, 29, 567.

Twenty three cases of drug resistant gonococcal arthritis are reported. Of these 10 were treated with sulfonamides and artificial fever in the hypertherm with the following results: 4 were cured and the remainder showed either considerable or partial improvement. Fifteen were treated with sulfonamides and fever artificially induced with intravenous typhoid vaccine with the following results: 6 were cured, 6 were either considerably or partially improved, 3 were not improved, and 2 of the last group were subsequently treated in the hypertherm with good results.

The results with both of these methods were encouraging. The use of the hypertherm is preferable to the use of vaccine. The most important consideration however is early treatment. Hence if the hypertherm is not available, combined vaccine and sulfonamide therapy should be instituted without delay.

It is emphasized that specific therapy does not supplant the regular methods of management of arthritis, which include bed rest, special diet and physiotherapy. Specific therapy is used in addition to these and results in a much greater percentage of cures and in the restoration of joints to useful function.

JOHN A. LOEF, M.D.

Koch, R. A., Haines, J. S., and Hollingsworth, W. Y.: Penicillin in Gonorrhea Treatment and Control. *J Am M Ass.* 1945, 129, 407.

The authors' results do not justify the belief that penicillin is an easy infallible cure for gonorrhea. Penicillin will cure most cases of gonorrhea, but cure is not necessarily accomplished by the first course of the drug or by penicillin alone. Supportive treatment, such as pyrotherapy and sulfonamides is necessary at times. Penicillin failures are frequent enough to warrant diligent search for gonococci following medication, for absence of clinical symptoms is not proof of cure.

Two groups of cases, one under hospital conditions for 8 days and the other under clinic conditions for 9 weeks are compared. The minimum hospital criterion of cure was two negative consecutive cultures obtained by prostatic massage, the last one being made at least 96 hours after completion of the medication and preceded by the provocative passage of sounds. The minimum clinic criterion was three consecutive negative cultures with one week between cultures. The taking of one follow up culture is not conclusive or adequate evidence of cure.

Fourteen per cent of 485 patients treated with an initial course of 200,000 units of penicillin were not cured. Patients with gonococcal epididymitis or prostatitis responded as well to penicillin therapy as those without such complications.

Penicillin is unquestionably the most valuable therapeutic agent thus far available for the treatment of gonorrhea. The medical profession must be aware of the limitations of penicillin therapy, the possibility of producing a carrier state, and the social factors related to the spread of the disease.

DAVID ROSENBLUM, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Bowden, R. E. M.: *Muscle Changes in Denervation and Re-Innervation*. *Brit. M. J.* 945: 487

The muscle changes in denervation and re-innervation are considered from the point of view of histology, electrical reactions, electromyography and the treatment of paralyzed muscles.

In the matter of structural changes, in the early stages (1 to 3 months after denervation) there is a loosening of the compact arrangement of the muscles and an apparent numerical increase of the nuclei; there is some stasis of the blood, the nerve fibers undergo Wallerian degeneration, and the empty Schwann tubes and empty motor end plates remain. After 3 months the muscle fibers atrophy and are replaced eventually by fat and connective tissue; ghosts of muscle fibers, a few capillaries, and the larger nerve trunks may be seen surrounded by fibrous tissue, a few scattered connective tissue tubes containing granules may be all that remain of the muscle fibers. However the changes are predominantly those of atrophy and not of degeneration, and up to one year after denervation it is possible to expect a fairly good degree of functional recovery; from then on the prognosis deteriorates, and as a rule after 3 years the prospects are exceedingly poor. There are, however, notable individual variations: sex, age, mobility of the limb and physical therapy influence the rapidity of the changes.

With regard to the electrical reactions, Erb's reaction of degeneration develops, faradic stimulation is lost and the threshold to galvanic stimuli rises with loss of contractile substance and may finally disappear altogether if atrophy is advanced. The failure to elicit a galvanic response in the absence of edema indicates serious change in a muscle.

On the subject of electromyography the author notes that for about from twelve to twenty-eight days after denervation there is no recordable electrical activity in human muscle on attempted movement or at rest from twelve to twenty-eight days after denervation, however, fibrillation does occur; this is shown by rhythmic, fine spikes on the tracing, which are totally unrelated to attempted voluntary contraction. Fibrillation persists as long as any contractile denervated fibers remain or until re-innervation is taking place.

Faradic stimulation is useless; the denervated muscle however responds to galvanism, and this is, therefore, one method of treatment. Electrotherapy not only should be regular and adequate but should begin as soon as possible after injury. Physical therapy is also of value in the prevention of contractures in the paralyzed muscles, daily movement throughout the whole range of the joints of the limb should be carried out, and splinting of paralyzed

limbs is never done to obtain immobilization unless there is a fracture or an unhealed wound.

However, whatever the treatment, the degree of functional recovery will depend on the nature of the lesion in the nerve. When the trauma or lesion to the nerve has not been sufficient to interrupt the supporting tissues of the nerve, although the trauma has been sufficient to cause complete peripheral degeneration of the axons, good powerful independent muscle action may be restored, but the pattern of innervation will be slightly abnormal. When, however, the nerve has been more seriously damaged there may be partial disruption of the Schwann tubes and scar formation; then there will not be as even an advance of regeneration axons and some permanent weakness and atrophy may be expected. In complete division of the nerve no recovery can take place without surgical intervention, which should be undertaken as soon as possible. Even so, some scar tissue will result at the suture line, with unavoidable confusion of the axons at this point, the number of nerve fibers reaching the end organs being thus diminished.

Motor unit action potentials may precede recovery of voluntary function by as much as 3 months; this observation in isolated instances, nevertheless, is no guarantee that further re-innervation is going to occur. Still, the finding of both fibrillation and motor unit action potentials indicates a partial or recovering degenerative lesion of the lower motor neuron.

A good functional recovery is possible while the electrical reactions are still abnormal.

JOHN W. BENDIS, M.D.

Jackson, E. C. B., and Seddon, H. J.: *Galvanism and Denervated Muscle Atrophy*. *Brit. M. J.* 1945, 485.

The results of electrical stimulation in the treatment of lower motor neuron lesions in general warrant the formulation of certain conclusions:

1. Muscle atrophy begins very soon after denervation and at first proceeds rapidly; then it gradually slows down as the time after denervation increases.

2. Interstitial fibrosis is a constant feature of denervation atrophy and it follows that the greater the atrophy and the fibrosis, the poorer the ultimate functional recovery. It follows that if atrophy can be prevented or controlled there is a greater likelihood that recovery will be satisfactory.

3. As yet there is no evidence that fibrosis is irreversible. The treatment to prevent it should be started as soon as possible after denervation and continued until re-innervation has occurred.

4. The precise nature of denervation atrophy is still unknown. Disuse and a consequent impairment of nutrition undoubtedly play an important part.

Fibrillation has been regarded as an important factor in throwing out and causing atrophy of the de

5 It has been conclusively shown that muscle wasting can be controlled to a very considerable extent by repeated electrical stimulation with a stimulus of comparatively long duration Galvanism has several disadvantages but it is the only type of stimulus of long duration generally available it was used in the investigation.

6 The treatment must be intensive both in the strength of the stimulus and in the number of contractions at each session and it must be continued over a long period to be effective.

7 Galvanism is of greater value in the prevention of wasting when it is applied early It has been reported that even the most intensive treatment did not altogether prevent atrophy

8. In the treated muscle the muscle fibers remain comparatively large. The interstitial tissue does not increase to any great extent and if reinnervation occurs, functional recovery is good. In untreated muscle the fibers shrink rapidly fibrous tissue appears between them, and recovery is poor

The rate of wasting in man after denervation is unknown. Adequate stimulation is limited by the large size of many muscles and other factors. This article describes the end results when 164 patients were examined in 92 of whom it was possible to obtain readings with sufficient frequency to be of value Of these 54 were suffering from complete nerve lesions The results are based upon the findings in these 54 cases Ulnar paralysis was present in every case in 18 per cent of those treated with galvanism and in 20 per cent of those not so treated, there was also paralysis of the muscles of the hand supplied by the median nerve.

Half of the cases were treated with galvanism and the other half without galvanism. Five charts are presented which show that in each period up to 400 days there was a steady loss of volume in the untreated muscles the rate of loss gradually diminishing until after 400 days when there was little change Galvanism was not effective during the first 100 day period Galvanism was almost completely effective in preventing wasting at all other times. There is no doubt that the volume of the hand is better maintained when the retarded muscles receive regular galvanic stimulation.

The beneficial effect of galvanism is most noticeable early rather than late after denervation. It follows that the earlier treatment is started the better the result. Galvanism at best prevents a decrease in the muscle volume. It follows that what ever has been lost from delay cannot be regained During the first 100 days, galvanism does not prevent wasting. It only retards it. Without galvanism, wasting proceeds faster in the first 100 days than at any other time. It is never too soon to begin galvanic stimulation. If the paralyzed part must be enclosed in plaster windows should be cut to permit early application of electrodes to affected muscles

The cases in this study were treated six times a week. Recordings were also made in cases treated three times a week. In addition recordings were made when there was considerable variation in the technique The good results were in direct proportion to the amount of treatment. Galvanism is of real value and success depends largely on the frequency of treatment. The treatment consisted of the application of 90 stimuli per day for 6 days a week The stimuli were strong enough to produce a brisk contraction They were given at the rate of 30 per minute with an interval of 1 minute between each group of stimuli to permit recovery from fatigue

RICHARD J. BENNETT JR. M.D.

Goodnick, L. T.: Solitary Myeloma; Review of 61 Cases. *Radiology* 1945 45 385

The prognosis of solitary myeloma is much better than that of multiple myeloma. Judicious irradiation produces relief of the symptoms and prolongs life.

Sixty-one cases in the literature are reviewed of this number 2 were the author's The average age of the patients was 50 years. The ratio of males to females was 2 to 1 The ilium femur humerus and thoracic vertebrae were the most common sites involved The chief complaint was a localized pain gradually increasing in severity Pathological fracture under increased stress and strain or trauma was frequent A palpable mass was present at times Solitary myeloma did not produce a generalized weakness and anemia as seen in multiple myeloma Hyperproteinemia, renal damage, and low blood pressure were rare.

Roentgenologically there are two types of solitary myeloma. The first resembles, and is frequently interpreted as a giant cell tumor The lesions are cystic and trabeculated within the medulla of the long bones or pelvis the cortex is expanded and pathological fractures are frequent. The second type is characterized by bone destruction. The pathology in both types is plasma cell myeloma.

All types of therapy have been tried Forty three cases were treated by irradiation following biopsy and curettage. As many fields as possible were used and the dose was fractionated from 300 to 500 r per portal for a total dose of from 1,000 to 3,000 r The course of therapy could be repeated whenever necessary Relief from symptoms was obtained in all but 2 cases. In 39 cases recalcification was demonstrable with x rays. Generalized spread occurred in 14 cases.

In this series 27 patients survived and 16 died Of 15 who died (1 died of a cardiac lesion) all but 1 lived more than 2 1/2 years from the onset of the symptoms. The average duration from the onset of symptoms was 7 years, and the lapse of time from hospital admission to death was 3 years and 9 months for the solitary myelomas In contrast to 14 months for the multiple myelomas.

Most authors believe that the duration of life is dependent on the transition of the lesion from the

solitary, the multiple type of myoma. Solitary lesions tend to be benign and clear away, whereas multiple lesions are malignant.

MAURICE D. SACHS, M.D.

Koch, S. L.: Injuries of the Hand. *Q Bull Northwest Univ Med School* 1945 9 365.

Simple principles of treatment of hand injuries, early and late, are concisely reviewed and pointedly illustrated.

Immediate cleansing of the area surrounding the wound, then of the wound itself, with soap, water and saline solution prepares a clean field where restraint in débridement is essential. Only if the wound can be closed for primary healing (by skin graft or pedunculated flap if necessary) can deep structures safely be repaired. Fractures may be reduced, but no nerve or tendon suture should be done without assurance of wound healing by primary union. Concerning local chemotherapy with sulfonamides the author quotes Meleney's report and War Department Directives which indicate that extensive clinical trial has proved its ineffectiveness.

Satisfactory late repair of compound injuries rests on three basic requisites which must be faithfully fol-

lowed in spite of all pressure on the surgeon for speed: (1) superficial and deep tissues must be free of infection; (2) all inflammatory reaction and edema must be gone from the affected area; and (3) the general condition of the patient must be optimum for prompt healing of extensive surgical wounds. The period of waiting for these conditions to be realized is important and should be utilized to bring all factors in the final effort to an optimum state. The normal status of the circulation, free joint motion and good muscle tone are essential to a satisfactory end result and all are stimulated by active motion in a warm water bath. Splints are needed to support paralyzed muscles and prevent stretching and can also be used with gentle traction to overcome contractures already present.

A normal soft tissue covering for the injured part must be prepared to replace thin scar which in itself causes contractures and cannot be used to cover deep structure repairs. Combined nerve and tendon injury is frequent and repair should be undertaken as a single project to conserve tissue and time. Current literature on this subject is cited.

Essentials for success in this type of surgery are that the wound heals by primary union, a minimum

Fig. Ventilator fan injury of the right hand. The thenar and hypotenar muscles were severely lacerated, the metacarpophalangeal joint of the thumb was held open, and the ulnar nerve and blood vessels were avulsed with flap. The index and middle fingers were almost completely ruptured at the proximal interphalangeal joints. Immediate cleansing, excision of the ragged and torn tissue, repair of the joint capsule of the thumb, suture of the ulnar nerve, and closure of wound without drainage were done. Left, Immediately after injury. Right, At primary dressing, 6 days later.

Fig. 3 The technique of substituting a free tendon graft for hopelessly injured flexor tendons. A, Incision. B After the fibrosed flexor tendons have been excised, free grafts are drawn through the carefully preserved tendon sheath and a guide suture is carried around the distal phalanx through a shallow tunnel made with a sharpened aneurysm needle. C, The free ends of the two tendons are smoothly united through the tunnel, and the graft is drawn taut, by tension on the tendon first drawn through the tunnel, and the line of suture comes to lie in the midline on the dorsum of the distal phalanx. D Fine silk sutures between the tendon graft and the stump of the profundus help to make the attachment of the graft to the distal phalanx secure. E, F, Suture of the proximal end of the graft to the proximal segment of the flexor profundus. Incision in the finger is closed before suture of the graft to the profundus is carried out.

of inflammatory reaction to surgery is incurred and that the postoperative wound be kept at rest so that sutured nerves and tendons are relaxed until firm union has taken place.

Incision may be planned to include excision of an old scar and thus avoid multiple scarring. Closure over repaired nerves and tendons must be made by means of a reflected flap so that the skin and subcutaneous tissue continuity remains uninterrupted over the deep suture lines. Such closure aids in preventing adhesions by imitating nature in surrounding the nerves and tendons only with areolar tissue. Foreign material of various sorts has proved to initiate scarring and adhesions and thereby inhibit free gliding on which normal function depends.

Tendon grafts are useful to bridge separations particularly of severed flexor tendons within the digital sheaths and may be taken from the long extensors of the foot uninjured portions of the flexor

sublimis or the palmaris longus. Problems arising in the use of tendon grafts are discussed and the technique used is described and illustrated.

It is best to remove the distal fragment of the flexor profundus and fix the graft directly to the phalanx. To facilitate freedom of movement, the graft is carefully dissected from its bed with an accompanying thin layer of areolar tissue. An adequate incision is used to avoid traumatizing the graft in securing it which reduces the fibrous reaction and subsequent scarring.

The tendon is held in place on the palmar surface of the finger by a part of the digital fibrous sheath or by a new annular ligament made from a free slip of tendon. The degree of tension at which the graft should be sutured to the proximal fragment is difficult to describe but it should approximate that of the normal physiological state this may be obtained by attaching the graft snugly when the wrist

and fingers are maintained in the flexed position. Postoperative immobilization must support the tissues with a minimum of tension at the suture line until firm healing occurs, usually in from three to four weeks. Too early attempts at motion provoke additional inflammatory reaction; therefore gentle active motion is withheld for from two and one half to three weeks. Paralyzed muscles need continued protection against stretching until nerve regeneration is complete in order that the integrity of their function is maintained.

FRANCIS E. BRIDGEMAN, M.D.

Platt, A. D.: Post Traumatic Para Articular Calcifications and Ossifications of the Ankle. *Am J Roent.* 1945 54 348.

Post traumatic calcification of a joint is important and frequently encountered in military personnel. Although calcification of most joints has been described little or no mention has been made of it in the ankle joint.

The etiology and chemistry of para-articular calcifications as well as anatomy of the ankle joint are discussed. In most instances, trauma is the predisposing factor. Immediate roentgen films may reveal only a soft tissue swelling. Serial roentgenograms serve to explain and aid in making a final diagnosis. Within 3 or 4 weeks following the initial injury linear calcification may be seen parallel to the posterior lip of the tibia, the anterior superior tibia, or lateral malleolus. Calcification may be seen also in the interosseous space. There are two types of calcification: evolutive, which appears fuzzy and has hazy margins with varying degrees of opacity in the adjacent connective tissues and stabilised which is a mature contracted, well defined density.

Treatment is conservative: immobilization and physical therapy. Sedation may be employed for pain. In the military services, it is wise to excuse these patients from marching and give them office positions. In severe instances anesthetic injections have been used with good results. Radiation therapy also has been used with favorable results. In most cases, full function of the ankle is never restored, and calcification may persist and be followed by fusion. Although there have been reports of cases of spontaneous regression of calcium, they are very rare.

MAURICE D. SACRE, M.D.

Horn, C. E.: Acute Ischemia of the Anterior Tibial Muscle and the Long Extensor Muscles of the Toes. *J Bone Surg.* 1945 27 615.

The author presents 2 case reports describing a peculiar type of vascular disturbance, a localized ischemia of the anterior tibial muscle and the long extensor muscles of the toes.

The characteristic clinical symptoms and findings are sudden onset of severe pain in the anterior portion of the leg, rapid development of swelling over the anterior fascial compartment, mild to intense erythema and glossiness and slight to complete peroneal nerve involvement.

The histological changes are identical to those occurring in Volkmann's ischemia. The vascular change is a fibrosis of the media, adventitia, and the periarterial tissue of the anterior tibial artery and ensuing occlusion.

The pathogenesis is obscure, but may be explained by repeated overwhelming physiological demands upon the anterior tibial artery for example, during military drill. Because of the anatomical arrangement, the musculature of the anterior fascial compartment is particularly vulnerable to circulatory disturbances. Idiopathic clawfoot may have its origin in insufficiency of the anterior tibial artery with ischemic contracture.

The treatment consists of early block of the lumbar sympathetic ganglia and early complete vertical incision of the anterior fascia crura. Arterectomy advocated by Leriche, should be performed if phlebotomy does not return to the anterior tibial artery. The authors state that Leriche believes that the elevated artery becomes a diseased sympathetic nerve, inducing vasoconstriction in the collateral network. He has demonstrated the increase in the collateral circulation following resection of the diseased artery.

DANIEL H. LEVINTHAL, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Johnson, R. W., Jr., and Lyford, J., III: The Treatment of Benign Giant Cell Tumor in the Lower Third of the Femur by Curettage and "Tele-scaping" the Fragments of Bone. *J Bone Surg.* 1945 27 557.

In 1936 a patient suffered from a giant cell tumor of the femur and had an operation in which one fragment of the femur was telescoped over the other fragment. The original operation met with permanent success and since that time the authors have employed this procedure in a series of 5 similar cases.

Case 1: White female, age 23, in whom this procedure was carried out. The final shortening was $3\frac{1}{4}$ inch.

Case 2: White female, 38 years of age, with a final shortening of 1 inch.

Case 3: White female, age 22, with a final shortening of 3 inches.

Case 4: Colored woman, 28 years of age, with a final shortening of $1\frac{1}{4}$ inches.

Case 5: White woman, 25 years of age, in whom the final shortening was not noted.

The operative procedure consists of exposing the involved area of bone in the distal femur and cutting a window in the thinnest part of the cortex. The tumor is removed by curettage. The cavity is canalized with pure phenol and washed out with alcohol. The remaining cortex is divided and the distal fragment is forced up around the end of the shaft of the bone by telescoping the fragments and filling the cavity with the end of the proximal fragment. No packs or drains are used. A plaster hip

SURGERY OF THE BONES JOINTS MUSCLES TENDONS

space is applied. There is shortening of the leg depending upon the size of the cavity.
This method permits removal of the tumor in cases in which the articular cartilages of the knee joint are intact. Good results were obtained in all cases.

FRACTURES AND DISLOCATIONS

Joell, A. P.: Traumatic Diastasis of the Symphysis Pubis by Muscle Action (Myotomoclasia de la sínfisis pública por acción muscular). *Rev Bras Soc Cirurg* Curitiba 1915 6 136

Diastasis of the pubic bone involves injury of the sacroiliac joint. When the separation is not more than 30 mm. there is only rupture of the ligament of the sacroiliac joint, when it is between 40 and 80 mm. there is total rupture of both the anterior and posterior ligaments. Four kinds of possible displacement in diastasis of the pubic symphysis are described—vertical, transverse, sagittal, and mixed. Pure traumatic diastasis of the pubic symphysis is rare. Among 13,000 cases of fracture Taylor saw 73 of fracture of the pelvis and 10 of diastasis of the pubis without fracture. Such cases of diastasis are generally caused by muscle action. The muscles that produce the diastasis are those of the internal region of the thigh with the leg fixed in hyperextension and hyperabduction.

The clinical diagnosis may be suspected in cases with violent contusions especially of the pelvis associated with serious traumatic shock and signs of lesions of the symphysis and sacroiliac joints. Direct roentgenography confirms the diastasis. In cases of descent of the injured side the roentgenogram shows an apparent ascent of the normal side. The spinopubic measurement is important, that is from the spine of the pubis to the anterosuperior iliac spine. This measurement is small on the uninjured side while on the injured side it increases with the degree of the diastasis.

Surgical treatment is rarely indicated as the pelvic treatment is generally gives very good results. Two cases are described. The first was of the descending variety in which the roentgenogram showed apparent ascent on the normal side. Continuous vertical traction was applied to both sides bringing this side down, but with the feet pressing against the foot of the bed, it exercises counter pressure on the other side and pushes the descended limb upward. In the second case instead of continuous contralateral pressure the head of the bed was raised, the left leg flexed and the right leg on the injured side rested against a block at the foot of the bed. The weight of the body as it slid down the inclined plane of the bed acted on the posterior part of the coccyx and pushed the displaced bone upward. Both of the cases are illustrated. (While anatomical restoration was not complete the functional results were excellent.)

AUDREY G. MORGAN, M.D.

Collom, S. A., Jr.: A Comparative Study of 100 Fractures of the Shaft of the Femur in Which One-Half Were Treated with Penicillin. *Ann Surg* 1945 121 773

The author presents 100 consecutive cases of femoral fractures observed in a general hospital in Italy. Uninterrupted treatment was rendered until the patients were evacuated to the United States for rehabilitation. Eighty-two cases were battle casualties and the remainder were accidental injuries. The former before reaching the general hospital had received shock therapy and primary wound treatment, including excision of damaged tissue and immobilization in a splint cast or a Tobruk splint in an average time of 16 1/2 hours after injury. Seventy-five per cent of the compound fractures of the femoral shaft were severely comminuted and involved from 2 to 8 inches of bone. Fifty-one per cent were fractures of the middle third, 29 per cent of the distal third and 20 per cent of the upper third of the femur.

The reparative method of reduction was that of skeletal traction. Tibial traction was reserved for the lower and middle thirds of the femur with Kirschner wire through the distal femoral fragment to control occasional posterior bowing of the lower fragment.

The authors have conveniently divided their cases into four groups.

Group 1 consists of 20 battle casualties treated without wound closure or penicillin of which 17 were penetrating thigh wounds and 3 were of the perforating type. Initial care was rendered within 25 1/2 hours after trauma. Because of definitive treatment of the wounds was not permitted secondary treatment localized abscesses, blood transfusion, and drainage of this group. In 17 cases the average time for wound healing was 8 1/2 weeks. The 3 other cases had healed union with fair alignment and presented poor results. Bony union was obtained in 17 cases.

Group 2 consisted of 50 compound fractures treated by wound closure and penicillin therapy in addition to débridement and fracture alignment. They were subjected to fasciotomy wound closure skin graft (when warranted) and obliteration of dead space to prevent pus pockets. Each patient was kept on penicillin until wound healing was progressing satisfactorily.

Group 2 A. Nine battle casualties which were treated the same as the cases in Group 1 developed severely comminuted, 3 moderately so and 1 was a transverse fracture. Seven casualties had sustained penetrating wounds and 2 perforating wounds. Callus formation was evident in 4 cases after 8 weeks. Skeletal traction was maintained for an average of 8 weeks. The remaining 5 cases presented poor results.

Group 2 B. In this group there were 41 patients. Thirty of these sustained severely comminuted fem

TABLE I RESULTS OF TREATMENT

Group	N. of Cases	Results		
		Good	Fair	Poor
	10		5	5
	9			4
	4	3		
	8	1		

oral fractures, and 8 moderately comminuted femoral fractures. 2 had oblique fractures and 1 had a transverse fracture. Each patient received approximately three million Oxford units of penicillin either before or upon entrance to the hospital. Twelve hours had elapsed before initial surgery was done. Reparative surgery was instituted 9 days after the injury. The soft parts healed in 4 or 5 days. Callus was noted in 5 weeks and bony union ensued after 11 weeks. Good results were obtained in 38 cases.

Group 3 consisted of 12 cases in which wound closure was performed by the authors without the use of penicillin. In addition to the general treatment, there was delayed primary closure without drainage in this small group. Initial surgery was performed in 13 hours and reparative surgery in 6 days. Callus formation was noted in 6 weeks and firm bony union in 10 weeks. Good results occurred in 11 cases and a fair result in 1 case.

Group 4 consisted of 18 simple femoral fractures, 4 of which did not respond to skeletal traction. These were subjected to open reduction, proper alignment being maintained with metal plates. The results were rated as good in all of the cases.

In conclusion the author maintains that penicillin and blood are of paramount importance in the prevention of sepsis and local infection. If however adequate preliminary surgery is not performed they alone are not a panacea. Reparative surgery of the soft tissues consisting of secondary débridement and closure instituted between the fifth and tenth days, enhances wound healing. The author also believes that the majority of femoral fractures can be treated by skeletal traction when indicated he recommends open reduction of simple as well as of compound fractures.

Sorondo, J. P., and Ferrá, R. L.: *Knee; Fracture of the External Tuberosity of the Tibia (Rodilla fractura de la tuberosidad externa de la tibia)*. *Rev. Is. méd. argent.* 1945 59: 1-57.

Fracture of the lateral tuberosity of the tibia is caused by a violent valgus deviation of the knee generally accompanied by torsion while the knee is in extension and slight flexion. The chief fracture line is directed outward, downward and forward. There may be secondary fracture lines.

The symptoms are pain at the site of the fracture, loss of function, swelling, hemarthrosis, and ex-

cessive lateral mobility. The roentgenogram shows the fracture line and fragments. The internal fragments may not be visible because they are made up of joint cartilage. Surgical treatment is indicated in all cases in which the joint surface is involved. The operative technique is described in detail and illustrated with photographs and roentgenograms. Absolute asepsis is necessary. Ordinary surgical asepsis is not sufficient. The fragments must be kept in place by some foreign material, such as a nail, a screw or a bolt with a nut on each end. A plaster cast is kept on for 2 or 3 months, after which massage and active and passive mobilization of the knee is begun. After 3 or 4 months the patient may sail with a cane if the x-rays show solid bone callus.

Within the past 25 years the author has operated on 8 cases. The late results cannot be reported because the time has been too short but the early results show that the disadvantages of operative as compared with nonoperative treatment are the danger of infection, and necrosis of the fragments. These can be prevented by the strictest asepsis. The advantage of operative treatment is better reduction. There is no danger of postoperative rigidity as the internal lateral ligament and the cruciate ligaments are generally loosened by the trauma which caused the fracture. This causes a certain degree of lateral instability of the knee but, on the other hand, it favors mobilization when the cast is removed.

ALBERT G. MORGAN, M.D.

ORTHOPEDICS IN GENERAL

Woolley P. V., Jr., and McCammon R. W.: *Bone Growth in Congenital Myxedema*. *J. Pediatr. S. Louis*, 1945 7: 19.

The authors state that the chronologic appearance of ossification centers is a useful index to thyroid function in infancy but is too slow for use in the control of therapy in the young cretin. Normal linear bone growth is suspended in the absence of thyroxine, and roentgenologically visible changes occur within three weeks of the beginning of the administration of thyroid extract. A curve of the normal growth rate of the radius during the first two years of life is used as a standard for comparison. With the radial growth rate in cretins before and during the administration of thyroid extract. Dense calcification at the epiphyseal plate, absence of carpal bones, and short radii are the roentgenologically recognizable stigmata of cretinism which are apparent before the clinical picture is clear-cut.

The findings in 3 patients from 2 to 4½ months of age are described and in 2 cases correlated with x-rays of radial growth resumption during thyroxine extract therapy. Radial growth in these cases is initially more rapid than the established norm, but levels off once the average growth is attained. New bone forms distal to the densely calcified bone near which is gradually replaced and disappears.

This information provides a means of accurately regulating the thyroid treatment of cretin by

monthly x ray studies, and of establishing the diagnosis of cretinism in infants under 2 years of age

FRANCIS E. BRENNICK, M.D.

Berman J. K.: Intercapulothoracic Disarticulation of the Arm. *Surgery* 1945 18 356

Intercapulothoracic disarticulation means the removal of the entire arm and shoulder. This includes the scapula, the outer two-thirds of the clavicle and all attached muscles and fasciae.

The disarticulation permits the complete excision of all anatomic lymphatics and lymph nodes all related muscular and fascial planes and all involved axillary tissue together with the related bones. This may be done as a unit operation with less blood loss than in a radical mastectomy. The skin flaps are usually adequate so that skin grafts are ordinarily unnecessary.

The mortality rate of this radical operation is no greater than for ordinary amputations of the upper arm. Therefore aside from the disfigurement and inconvenience produced there are no objections to its use. Certainly these are inconsequential objections when compared with the additional chances for cure. If a portion of the arm must be removed then the inconvenience is not much greater and the

disfigurement though unsightly may be rectified by proper shoulder pads.

The author defines the indications for the procedure describes its technique and calls attention to the importance of this old operation under modern diagnostic and surgical methods. Photographs and anatomical drawings photoroentgenographs and photomicrographs are presented. Five cases without operative mortality are reported. The operation may be safely done at any age. Soft tissue growths gave better results than lesions in bone. The former found in older patients were carcinomas.

The value of preoperative roentgen therapy has not been determined but roentgen therapy is advised because it may lessen the chance for metastasis and local recurrence. It may reduce the size of radio-sensitive or infected growths and thereby facilitate complete extirpation.

None of the patients had local recurrences. The 3 deaths occurred from internal metastases. They all occurred in patients with sarcoma.

The end-results of intercapulothoracic disarticulation are encouraging. Available statistics though meager prove that the operation offers a chance for cure in cases ordinarily considered hopeless.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Freeman, N. E.: Secondary Hemorrhage Arising from Gunshot Wounds of the Peripheral Blood Vessels. *Ann. Surg.* 1945 21 631.

Secondary hemorrhage following gunshot wounds in the first world war was a common complication. Although present methods of débridement, immobilization, and chemotherapy have resulted in a striking reduction in the frequency of this complication, the occasional occurrence of severe bleeding often with disastrous consequences, still make this problem an important one. The author arrives at the following conclusions insofar as his experience was concerned.

The incidence of secondary hemorrhage in 2,163 cases of gunshot wounds of the neck and extremities was 2.06 per cent. Of the 23 patients, 15 bled from wounds of major blood vessels. The present study is based on an analysis of these 15 cases.

Laceration of the arterial wall, rather than complete severance, was found in the 23 patients whose wounds were explored. There were 3 deaths in the group. Two patients developed gas gangrene and 1 of these died. Ligation of the femoral artery resulted in ischemic gangrene requiring amputation in 1 case. Recovery took place in the remaining patients.

A history of severe or recurrent hemorrhage in the forward area, or the presence of severe anemia on admission, is indicative of injury to a large blood vessel. Secondary hemorrhage is to be anticipated in cases with these findings. In spite of a demonstrated large opening in the main artery of the extremity the peripheral pulse was normal in 6 cases, reduced in 2 and absent in only 1 patient. Periarterial hematoma was found in 4 individuals, but pulsation and bruit was present in only 2 of these. Peripheral edema or diminished sensation in the distal parts of the extremities was present in three-quarters of the cases with lacerations of the blood vessels of the extremities.

One case of rupture of an arteriovenous aneurysm of the neck is reported. In a second case of secondary hemorrhage from the neck, the bleeding, which was definitely venous in origin, was controlled by suture of the tissues over the bleeding point. Both patients recovered.

In all patients the major artery was exposed by wide extension of the original wound. Suture of the arterial laceration was attempted on 2 occasions. It was apparently successful in 1 case. In the second case thrombosis at the suture line extended downward and contributed to the development of gangrene. In the remaining patients the artery was divided and ligated with No. 1 chromic catgut. No untoward results were observed after the use of this absorbable suture material.

The injection of alcohol into the region of the paravertebral sympathetic ganglia was performed in 4 cases with good results. In a fifth patient, procaine was repeatedly injected.

A small initial hemorrhage occurred in 7 patients before the severe blood loss which prompted operation. Attention is again called to this "red signal" as an "inexorable indication for exploration of the wound."

PAUL MEXNER, M.D.

Eaton, R. M., Czebrinski, E. W., and Smith, J. R.: Observations on Pulmonary Arterial Pressure and Peripheral Venous Pressure Following Arterial Blood Loss. *J. Thorac. Surg.* 1945 10 339.

This contribution represents the first of a series of studies concerned with pulmonary and circulatory changes resulting from simple peripheral arterial blood loss. During experimental studies by the authors on pulmonary lymph flow in which controlled arterial bleeding was instituted, very consistent lung changes, which were almost starting in their apparent import, were observed quite accidentally. Pulmonary edema and pulmonary hemorrhage were produced at will by the simple removal of moderate to large quantities of blood from the femoral artery the greater the blood loss, the greater the pulmonary damage. Inasmuch as great loss of blood is such a common occurrence on the battlefields of the world, a study of the physiological factors involved in this pulmonary change seems necessary.

The authors first report the results of their experiments with a large group of dogs in which 25 per cent of the blood volume was removed, for it was thought that the loss of this quantity would simulate a battle casualty. A second series of experiments with 20 per cent loss of blood volume was made to compare with an operative hemorrhage of about 300 cc. in an average human being. The methods of study are described in detail and the results are discussed at some length.

It would seem possible that the pulmonary congestion resulting from systemic arterial blood loss is the result of increased permeability of the alveolar endothelium, due to acute anoxia of the tissues. When the physiological events are reconstructed, as acute anoxia is apparent for many reasons. Breathing is noted to be rapid, deep and forced air hunger has been produced and carbon dioxide concentration is increased. With arterial hemorrhage, there is a true loss of blood volume and a decrease in available red corpuscles to carry oxygen. The heart rate increases in hemorrhage but cardiac output actually decreases. There is evidence that the circulation time is greater and that vasodilatation occurs. Besides these factors, there are certain experimental observations which show that deep, rapid, forced

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

235

respirations and anoxia can produce increased pulmonary transudation.

Pulmonary congestion resulting from acute arterial blood loss produces a block to normal circulation and an increase of pressure within the peripheral venous system, as well as within the pulmonary artery. This pressure is developed within the vessel its peak in from 50 to 60 minutes from the time of hemorrhage.

The observations presented here are consistent with those of the anatomic and clinical findings about "bomb blast lung," a pathological condition brought about by instantaneous overdistention of the alveoli most typical lesion of bomb blast injury to the chest wall. The rage and edema of the lungs and there is homoevidence of high venous pressures. Proof of this fact might make it desirable to try venesection as a life-saving procedure, as in the pulmonary edema of congestive heart failure.

The authors conclude that there is a gradual decline of these elevated venous pressures to a lower than normal level within 144 hours of the hemorrhage. Increased venous pressure during intravenous administration has been shown experimentally to elevate the venous pressure additionally.

HENRIET F. THURGOOD M.D.
NELSON, J. J.: Universal Vascular Compressor for the Development of Collateral Blood Circulation in Arterial and Arteriovenous Aneurysms. *U S Aev M Bul* 1945 45 1169

The use of modern firearms has led to an increase in blood vessel injuries and arterial and arteriovenous aneurysms. Since spontaneous recovery of these conditions is so rare, surgical operation is the only indicated means of treatment. The time of surgical interference is a controversial point. Some surgeons regard the second and third week after injury as the ideal time to operate, while others wait as long as three months.

Complete momentary ligation with sympathetic omy (Käther) incomplete ligation (Hilalated Mats, Allen) the operation of Eklital Sym (ligature inside the sac) the operation of Mats (obliterative or reconstructive) and vascular sutures for the preservation of vessel lumen have all been suggested for the treatment of arterial aneurysms and arteriovenous aneurysms.

Since pathological changes occur in the vessel walls, ligation of the blood vessel accompanied by dissection of the sac seems to be the preferred operation today. The operation is technically simple and practical regardless of pathologically simple and changes in the vessel walls. The danger of limb necrosis after ligation of the main arterial trunk is real as to percent of the cases in World War I showed this complication.

Surgeons have been working on the problem of preventing gangrene of the limbs after arterial ligation to decrease the number of amputations. Not

all arteries are equally affected. Ligation of the popliteal artery is particularly hazardous. Nearly 20 per cent of the ligations of the carotid artery threaten the patient with serious circulatory disturbances of the brain.

All surgeons agree that the necessity of primary development of a collateral circulation is of primary importance. Rather advocates sympathetic section, contrast baths and diathermy to improve the collateral circulation.

Mechanical compression of the arterial trunks is accomplished in most institutions with digital pressure by a doctor or nurse. This is tiring and practically of no value. It is not practical when several patients in the same ward suffer from aneurysms if the compression is entrusted to the patient it is usually not effective.

A vessel compressor has been devised to obviate these difficulties. Compression of the vessel is effected by a screw rod fastened in a block at the required angle by a globular nut. This block moves along the grooves of the upper arm of the clamp. The hand wheel can be removed when the desired degree of compression has been established so the patient cannot alter the pressure himself.

A constant or removable plaster bandage in which the clamp is fixed is applied to the patient. Compression of the common carotid is effected approximately at the level of the Chassaignac tubercle between the ends of the sternocleidomastoid muscle. The patient is kept recumbent with the head slightly elevated on a pillow.

Subclavian compression is effected between the clavicle and the upper part of the sternocleidomastoid muscle and the upper side of the clavicle. The patient should be recumbent with the head slightly elevated beneath Poupart's ligament, above the femoral artery. Compression of the femoral artery is effected just part of the pubis. The patient should be placed recumbent.

At first the compression is applied several times a day for from 10 to 15 minutes each time. Then for the subclavian and femoral arteries, compression may be applied for from 2 to 3 hours several times a day during the next week. For the common carotid great caution must be practiced at the beginning of the compression should be applied for only 10 to 15 minutes at a time. Careful watch must be kept for paresis or paralysis and other symptoms of circulatory disorders.

Just how a patient will react to carotid pressure never can be predicted, and a case is presented to show the possibility of a dangerous reaction. Other cases such as this primary ligature certainly would cause a serious circulatory disturbance in the brain. Other wounded patients bear common carotid pressure well and soon the artery can be compressed for long periods without unpleasant consequences or circulatory disturbances. One cannot guess in which cases compression of the common carotid for a long

time is safe. This can be ascertained only by careful observation at the time of compression.

In the course of compression the limbs may become cyanotic from proximal vein pressure. This is without dangerous after effects and may be counteracted by massage and warming. Carotid pressure may cause coughing from simultaneous vagus nerve pressure. If applied for a short time, compression does not cause painful sensations. If after 2 or 3 hours pain develops, it responds well to small doses of narcotics.

After the apparatus has been used it can be disassembled and the parts cleaned with alcohol and packed away. The block, groove, and globular unit must receive particular care. The clamp is left cemented in plaster but its groove must be cleaned well with alcohol.

To check the efficiency of compression, a sphygmographic record of the arteries, such as the common carotid or subclavian, may be made or digital palpation of the distal vessels carried out.

One patient completely recovered from an arteriovenous aneurysm after prolonged application of the compressor to the right subclavian artery. His case is reported.

In order to develop the collateral circulation, one must compress a single arterial trunk without disturbing the collateral paths.

Mistak vessel compressor is unfit for compression of the femoral artery immediately under Poupart's ligament, as well as of the subclavian or carotid arteries. The proposed vessel compressor allows compression of nearly all the large arterial trunks such as the common carotid, subclavian, and femoral arteries, but it cannot be used for direct compression of the iliac artery. When this vessel requires ligation the application of pressure to the femoral artery high under Poupart's ligament is recommended.

ROBERT R. BRIDLOW, M.D.

Whipple, A. O.: The Problem of Portal Hypertension in Relation to the Hepatosplenopathies. *Ann Surg* 1945 133 449.

This contribution is based upon experience and studies gained from the organization of the Spleen Clinic at the Columbia Presbyterian Medical Center in New York. In order to elucidate the pathogenesis, pathology, diagnosis and treatment of portal hypertension certain points in the anatomy and physiology of the circulation of the liver and spleen are reviewed in detail.

The amount of portal bed obstruction, and the type and site of obstruction are all variable factors in individual patients with portal hypertension. It is the discovery in the individual patient of these factors and their analysis that very largely determines the diagnosis, treatment and prognosis. Patients with portal hypertension may be divided into two main groups: group I, those having intrahepatic portal block, and group II, those having extrahepatic portal block. In the first group the cirrhotic, especially of the portal or Laennec type

are associated with portal block. The mutual influence of the portal and arterial pressures within the liver provides an important explanation for the rise of portal pressure in portal cirrhotics, and also explains the variability of portal hypertension in the cirrhotics and the presence or absence of gastrointestinal hemorrhage as an accompaniment of portal hypertension.

With regard to group II there are two types of obstruction seen in chronic occlusion of the portal vein and its main tributaries. The first is a replacement of the vein or its main tributaries with fibrous tissue with little or no canalization. The second is a transformation of the portal vein, its main tributaries, or the enveloping tissue into a cavernomatous mass of small tortuous vessels, a process spoken of as cavernomatous transformation of the portal vein. In the first type of fibrous replacement there are two causative factors. The most common is an organization into scar tissue of a thrombosis of the portal vein. The thrombosis may be the result of inflammation, trauma, or pressure from without by inflammatory or neoplastic tissue. The second causative factor is an extension into the left portal vein, or proximal to it into the main portal vein, of the obliterative fibrotic process that takes place at birth in the umbilical vein and ductus venosus as they empty into the left portal vein. This type of obstruction is rare but is seen in young children that begin at an early age to show portal block with splenomegaly and a Banti syndrome. The pathogenesis of cavernomatous transformation is not definitely known but it would seem logical that the etiology of this lesion is a variable one.

The collateral circulation in portal block has been classified as of two types, the "hepatopetal" and the hepatofugal. When the circulation through the liver is unobstructed and the block is limited to the portal vein the blood may be shunted through the hepatopetal collateral veins into the liver. In lesions causing intrahepatic block the hepatopetal circulation shunts a variable amount of blood from the gastrointestinal tract and spleen around the liver.

Both chronic intrahepatic block and extrahepatic portal block have been successfully produced in experimental animals. In the experimental animals and in many of the patients, portal bed block produces a fairly typical syndrome. This is true of the cases showing a splenomegaly whether the block is intrahepatic or extrahepatic. This syndrome consists of a variable secondary anemia, a leucopenia, a thrombocytopenia, a splenomegaly, and a tendency toward repeated severe gastrointestinal hemorrhage, most frequently associated with ruptured esophageal varices. The liver may be cirrhotic or normal, according to the site of the portal bed obstruction. This syndrome is frequently spoken of as Banti's syndrome. It is the author's present concept that Banti's syndrome is the result of mechanical obstruction to the flow of blood within the portal bed. In the cirrhotics there is a variable amount of portal

hypertension, determined by the amount of scar tissue in Glisson's capsule the relation of the pressure in the hepatic artery to that in the portal vein, and the extent of the hepatofugal circulation. For these reasons splenomegaly gastrointestinal hemorrhage, leucopenia, and thrombocytopenia are not always found in the cirrhotics. This syndrome is not characteristic of the biliary and cardiac cirrhotics. On the other hand if the extrahepatic portal block, from whatever cause, is sufficient to produce splenomegaly Banti's syndrome is nearly always present, and a normal liver is usually found even in the cases of long standing.

Patients with portal hypertension great enough to cause an enlarged spleen usually present leucopenia, thrombocytopenia, and secondary anemia of Banti's syndrome. There may be no history of gross gastrointestinal hemorrhage. The differential diagnosis from other splenomegalies is largely determined by accurate hematological studies. The site of portal block, as to whether it is intrahepatic or extrahepatic, can usually be determined by certain liver function tests. If the liver function tests are negative it is safe to assume that the block is extrahepatic. This does not determine the site of the extrahepatic block, although the history or the age of the patient may indicate it. The author has been unable to determine the site of extrahepatic block at the time of splenectomy in more than half of his patients although recently he has been able to demonstrate the block by diodrast venograms and roentgenograms made during the operation at the time of determining the portal vein pressures.

The therapy of portal bed block, both intrahepatic and extrahepatic, associated with Banti's syndrome is considered in the discussion of treatment. Three factors, the site of the block, the degree of portal hypertension, and the extent and competency of the collateral circulation determine the use of the spleen and the incidence of gastrointestinal bleeding. The two latter components of the syndrome are the usual indications for attempted surgical therapy. In the past, three lines of surgical attack have been followed: splenectomy, the establishment of a collateral circulation with omentopexy and the ligation of tributaries to the esophageal varices. If the portal block is in the esophageal vein the removal of the spleen results in a permanent disappearance of the Banti's syndrome. Unfortunately this site in the splenic vein is not common one for portal bed block. However even with the block in the main portal vein splenectomy provides relief for a variable time because of the removal of a large area of the portal bed and until the portal hypertension builds up again. The efficacy of omentopexy is questionable. If the operation is done in the presence of a well established collateral venous circulation in the abdominal wall the results in a few cases are encouraging but are probably due to Nature's efforts rather than to the surgeon's. Attempts to ligate the tributaries feeding into the veins of the cardia and esophageal varices

have been disappointing. Injection and coagulation methods to obliterate the esophageal varices have produced no improvement, since these methods shut off one of the chief collaterals between the portal and systemic circulation and increase the portal hypertension. The large number of patients with portal vein block and Banti's syndrome who had portocaval anastomosis but who continued to have recurrent gastrointestinal hemorrhage challenged the members of the Splenic Clinic to seek a more effective and permanent therapy.

Efforts to anastomose branches of the mesenteric veins to the spermatic, the ovarian, and the inferior vena cava by suture technique failed. When Blake and Lord developed the endothelial lined vitallium tube nonsuture technique for bridging large vessel defects it was decided to apply this method to portocaval anastomosis. With this principle, 10 of these major operations have been carried out, 5 by union of the splenic vein and left renal veins after removal of the spleen and left kidney. In the last 5 patients the portal vein was anastomosed to the inferior vena cava, end to side. All the patients have survived their operations. The results in 5 have shown such improvement that the application of portocaval anastomosis by the nonsuture technique is being extended to the nonfollow up period of at least three years to determine the value of these procedures.

JOHN L. LINQUIST, M.D.

Blakemore, A. H. and Lord, J. W. Jr. The Technique of Using Vitallium Tubes in Establishing Portocaval Shunts for Portal Hypertension. *Ann. Surg.* 1945 122: 476.

Since Eck first performed successful experimental anastomosis of the portal vein to the vena cava surgeons have been interested in the clinical application of the Eck fistula for the relief of portal hypertension. The rare reported instances of portal hypertension and the discouraging results of attempts at the establishment of portocaval shunts by suture and the discouraging results signify the technical obstacles to its clinical application. The development of the vitallium tube nonsuture method of accomplishing either splenorenal anastomosis or portocaval anastomosis has afforded a new method of accomplishing either splenorenal anastomosis or portocaval anastomosis. Splenorenal anastomosis is capable of handling a large volume of blood and has the peculiar advantage of eliminating a sizable portion (estimated at 40 per cent) of the total circulating portal blood volume by splenectomy. The authors' clinical experience thus far has been limited to end to end anastomosis of the splenic vein to the left renal vein. The facility with which an end to side anastomosis may be carried out with a vitallium tube anastomosis alternate method to the sacrifice of a kidney. The technique consists of mobilizing the spleen and preserving the full length of the splenic vein with minimum trauma during splenectomy. The splenic artery is ligated and the spleen is somewhat emptied of its blood. The splenic vein is ligated just at its

primary distal branching. The blood is then milked far proximalward in the vein and a rubber-shod clamp applied. Following removal of the spleen the stump of the splenic vein is opened, triangulated with clamps, and irrigated with normal saline solution.

The left kidney is removed, but a maximum length of the main renal vein is preserved for the anastomosis, and a rubber shod clamp is applied as far proximally as possible. The stump of the renal vein is treated in the same way as the stump of the splenic vein and a proper sized vitallium tube is selected. The end of the splenic vein is passed through the tube, triangulated and everted over the end of the tube. The vein is held in place by a ligature of silk placed behind a ridge on the tube. The intima covered end of the vitallium tube is introduced into the renal vein and a ligature is applied over the vein proximal to the ridge on the tube. A second ligature is used to approximate the renal vein snugly to the splenic vein near the end of the tube. The latter ligature prevents blood from penetrating between the two intimas. The clamp on the splenic vein is released and immediately following the clamp on the renal vein is released. It was necessary to resort to a vein graft in only 1 of the 5 cases.

The Eck fistula type of portacaval shunt has the advantage of size. An end to end anastomosis of the portal vein to the vena cava by the nonsuture vitallium tube technique affords an estimated blood carrying capacity from 30 to 40 per cent greater than a splenorenal anastomosis. In order to avoid the undesirable use of a vein graft it is necessary to mobilize the portal vein from its bifurcation at the liver to the origin of the splenic vein. The portal vein is mobilized, to protect the common duct and hepatic artery from injury and a rubber shod clamp is applied to the portal vein at the origin of the splenic vein. A transfusion ligature is placed around the portal vein at its bifurcation close to the liver, and the vein is transected distal to the ligature. The vena cava is mobilized from the level of the liver down past the entrance of the left renal vein to the upper level of the right renal vein and a clamp is placed but not tightened at this time. The portal vein is passed through a vitallium tube and cuffed over the end of the tube and ligated behind the holding ridge. The vein covered vitallium tube is now swung out from behind the common duct and over the vena cava, and a site for the anastomosis which will not result in angulation or compression of the vein is selected. Two purse string sutures of silk are introduced into the full thickness about the site chosen for anastomosis to form two circles the diameters of which are 4 and 6 mm. larger respectively than the diameter of the vitallium tube. A second clamp is placed at the upper part of the mobilized vena cava and the distal clamp is tightened to occlude the vena cava. A cruciate incision is made through the vena cava wall and the apex of each quadrant grasped with mosquito forceps. The veins are irrigated with

saline solution and the vitallium tube bearing the portal vein is advanced into the opening. The inner purse string suture is tied proximal to the ridge on the tube. To establish the blood flow the proximal clamp on the vena cava is released first, followed immediately by release of the clamps on the portal vein and the distal vena cava, respectively.

This article is based upon experience gained in the establishment of portacaval shunts in 10 cases (5 splenorenal anastomoses, and 5 portal vein to vena cava anastomoses). Convincing clinical evidence of portal hypertension should be procurable in the vast majority of cases preoperatively. One can accurately predict on the basis of liver function chemistry whether portal hypertension is due to intrahepatic (portal cirrhosis) or extrahepatic portal bed block. The variable origin of the coronary vein from the splenic or portal vein accounts for the presence or absence, respectively, of esophageal varices in congestive splenomegaly due to a block in the splenic vein.

Splenectomy alone as a treatment for congestive splenomegaly should be limited to those cases of splenic vein thrombosis in which the coronary vein arises from the portal vein, or if it arises from the splenic vein, to those cases in which the obstruction is distal to its origin. At operation in cases of congestive splenomegaly due to extrahepatic portal block, venous pressure readings are essential to determine the obstruction sites in the splenic vein. A normal reading from a branch of the superior mesenteric vein and an elevated reading from a branch of the coronary vein of the stomach would indicate a block in the splenic vein and suggest that the coronary vein originates from the splenic vein distal to the site of the obstruction. This evidence would make splenectomy followed by splenorenal anastomosis preferable to splenectomy alone. In a case of congestive splenomegaly in which the superior mesenteric pressure is normal, the splenic venous pressure elevated but the coronary vein pressure approximately normal, a splenectomy alone would be indicated. Venography following injection of diiodol in a branch of the coronary vein is useful in confirming the site of origin of the coronary vein. In most cases of cavernomatous transformation of the portal vein splenorenal anastomosis is likely to be the only type of portacaval shunt it is practical to use. It was found feasible in 1 case of atresia at the portal fissure in which the spleen had been previously removed to do a portal to vena cava anastomosis with a vein graft.

Every one of the 10 cases of portacaval shunts went through a successful postoperative convalescence. The interval following operation has been too short in some to judge the results. However, in 6 of the 10 cases the improvement has been so outstanding that it justifies continuation of the procedure. The Eck fistula operation is better tolerated by the patient, in all probability because of less blood loss during the procedure.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

LYMPH GLANDS AND LYMPHATIC VESSELS
David, P.: Hodgkin's disease (La maladie de Hodgkin)
Union med. Canada, 1945 74 1543

The author presents a table showing the details of his findings in a careful study of 30 cases of Hodgkin's disease. Jackson and Parker have described three types of Hodgkin's disease: Hodgkin's granuloma, Hodgkin's sarcoma, and Hodgkin's lymphoma. The prognosis in these conditions depends on the type of the lesions. If this classification should prove valid it is a very important contribution to the subject.

Neither Sternberg nor Reed discovered the cells which bear their names. The frequency of the disease increases with age. It is as yet impossible to say whether Hodgkin's disease is infectious or non-infectious. It is a borderline disease which makes it especially important. Gordon thought he had discovered a virus for it but was unable to prove it. Nevertheless his test is of some value. Poston discovered brucella melitensis in 14 consecutive cases and this may prove to be the causative agent. Prunius is a secondary symptom which is not very frequent. The author has seen three types of fever: it may be impossible to make a diagnosis of abdominal Hodgkin's disease.

There is no typical blood picture in the disease but yet the blood picture may be an aid in diagnosis. Eosinophilia is rare. Even if the clinical picture is very severe roentgen ray or radium treatment should be given. In selected cases surgical extirpation of the glands followed by roentgen or radium therapy has given very good survivals. Any visible hypertrophy of the glands should be examined at once by means of biopsy. The longest survivals have been seen in the cases of early removal of Hodgkin's glands.

AUDREY G. MORGAN, M.D.

Cherische, H.: Tumors in One of Homologous Twins; Hodgkin's Disease with Primary Skeletal Manifestations. *Am J Roent* 1945 54 479.

The author reports the fifth case of Hodgkin's disease in one of homologous twins. The first 2 cases in the literature were reported by the same author. The patient was a white female aged 5 years one right hip and right shoulder fever and loss of weight of ten weeks duration. On examination, aside from poor nutrition fever increase in the pulse and respiratory rates and leukocytosis manifestations of the disease were limited to the roentgen

Fig. 1. Hodgkin's disease in one of homologous twins (Healthy twin refused to take off shoes.)

findings of areas of rarefaction in the parietal region of the skull, the right clavicle, and the right ilium. Roentgen therapy to the right hip and clavicle was of no benefit and the child died one month after admission shortly after the onset of a bilateral pneumonia. Postmortem examination revealed Hodgkin's disease of the thymus cervical lymph nodes liver spleen bones and lungs with secondary emphysema and bilateral pneumonia. The patient a homologous twin was last examined four years and eight months after the onset of symptoms in the deceased homologous twin. Physical examination, including roentgenographic study of her skeleton and lungs showed no evidence of any pathological condition. EMMETT E. ARNHEIM, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Lovell, D. L.: Skin Bacteria; Their Role in Contamination and Infection of Wounds. *Arch. Surg.* 94:5 51-78.

Investigations were carried out to determine the type and number of bacteria gaining entrance to the wound during the course of routine operation and their role in the infection of the wound.

To determine the number and type of organisms gaining entrance to the wound during operation cultures were taken as follows:

1. After proper skin preparation a sterile sponge, thoroughly moistened with isotonic solution of sodium chloride was rubbed over the skin. The saline solution was then expressed from the sponge into a sterile container. All this solution was cultured by the pour plate method. After 24 hours of incubation, the number and type of colonies present were recorded.

2. Immediately after the incision in the skin had been made, towels were clipped to the edges to prevent, so far as possible, surface bacteria from getting into the wound. The wound was then irrigated with a small amount of isotonic solution of sodium chloride and the solution cultured by the method previously mentioned.

3. After the primary object of the operation had been accomplished the wound was again irrigated and the solution cultured.

4. After the wound had been closed the towels were removed, and the final culture was made from the surface of the skin.

Although there is no accurate method of recovering all the organisms in the wound or on the surface of the skin, the procedures used gave uniform results which were satisfactory for comparison. All operations were performed under bactericidal radiant energy to minimize contamination from the air.

Cultures were taken during 35 operations for inguinal hernia and during 115 operations of other types. Few organisms were obtained from the surface of the skin immediately after mechanical and chemical cleansing. Some of the cultures were sterile, but of those which grew organisms the greater number presented the staphylococcus albus. Other bacteria, including the staphylococcus aureus, the escherichia coli, and a nonpathogenic fungus, were present occasionally in small numbers.

In the second culture, it was shown that in most instances a few organisms were carried into the wound with the skin knife. They were of the same variety as those obtained from the surface of the skin were relatively nonpathogenic, and belonged to the resident flora.

The number of organisms obtained from the wound just before closure was considerably greater

than the numbers recovered in the first two cultures. This was probably due to the fact that the bacteria which gained entrance to the wound multiplied during the time of operation.

A large number of organisms were obtained from the surface of the skin after closure of the wound. This was thought to be due to the resident flora rising to the surface and multiplying during the time of operation.

The number and type of bacteria obtained from the surface of the skin immediately after mechanical and chemical cleansing did not vary greatly with the character or location of the operation. The number of bacteria removed from the wound before closure was greater in the operation for inguinal hernia than in the other operations. This was thought to be due to the presence of numerous hair follicles in this region which results in a larger resident flora.

During operations the skin should be considered contaminated at all times regardless of the preoperative preparation. In closing the wound the towels should be left in place until the wound is closed in the subcutaneous fascia. At this time the surface of the skin should be considered much more contaminated than at the time the original incision in the skin was made. The towels should then be removed, the surface of the skin cleansed with the antiseptic solution, and clean sterile towels placed over the area before the sutures are inserted in the skin. Stitch abscesses are best avoided by the additional precautions of early removal of the suture and the avoidance of tension. LUTHER J. FROST, M.D.

Starr, I., Mayock, R. L. and Battles, M. C.: Convalescence from Surgical Procedures. Studies of Various Physiological Responses to a Mild Exercise Test. *Am. J. Hyg.* 94:5 1-77.

The aim of the authors' investigation was to explore the possibilities of finding objective methods of demonstrating abnormalities present in convalescence after surgical procedures which would serve as an indication of the duration of the convalescent state and as a test of measures designed to shorten it. The authors believed that no abnormalities characteristic of convalescence would be demonstrable while the patients lay at rest, but they hoped that when the patients performed a task, abnormalities might manifest themselves. For this purpose a easy weight lifting test was devised which could be performed by the subject while lying in bed on his back and breathing from a spirometer designed to measure the basal metabolic rate. By this means oxygen consumption could be determined without gas analysis and both the rate and volume of respiration estimated from the spirometer record as well.

Oxygen consumption and volume, and the rate of respiration were determined before, during, and after standard exercise. The cardiac output (balistocardi-

diagram) and pulse rate were estimated before just after and 5 minutes after the same exercise. Measurement of the magnitude of the changes induced by the exercise revealed no significant differences which could be attributed to convalescence. However when attention was given to the duration of the changes induced by the exercise the increased oxygen consumption, respiration, and pulse rate declining to the resting level more slowly during convalescence than before operation.

The respiration and oxygen consumption of subjects at rest were not significantly changed during convalescence. The variability in the physiological response to exercise is so great that a test of the type used gives no promise of providing a satisfactory measure of the duration of convalescence in individual cases. However, the slow return to normal of the pulse rate, respiration, and oxygen consumption after exercise may have some value as an indication of persisting abnormality in certain individuals and will provide significant differences when data obtained from a series of 10 or more cases are averaged.

Enklins J. P.: The Effect of Postoperative Exercises and Massage on the Incidence of Pulmonary Embolism at the Chelsea Hospital for Women. *J. Obst. Gyn. Brit. Empire* 1945 52 480.

Postoperative exercises and massage were introduced at the Chelsea Hospital for Women in 1937 in an attempt to reduce the incidence of pulmonary embolism.

The incidence of fatal embolism following abdominal operations fell by more than 50 per cent in the subsequent 7 year period.

The deaths from embolism are reviewed with regard to general incidence, age of the patient, and type of operation. Some details of the exercises and massage employed are given and are followed by a short discussion with references to the recent literature.

JOHN J. MALOYER M.D.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Evans, E. I. and Bligden J. A.: The Rationale of Whole Blood Therapy in Severe Burns. *Ann. Surg.* 1945 122 695.

The main purpose of the authors study was to evaluate whole blood transfusion in the management of burn shock in the severely burned patient. Blood volume determinations in severely burned patients soon after the burn had been received indicated a decrease in the total circulating red cell mass. It is believed that this initial loss of red blood cells may account for a considerable portion of the "masked anemia" that appears in the post-shock period in many burn patients. Other than a deficit in the red cell mass soon after the burn is received the cause of

the early anemia in burn patients has not been disclosed by any studies made by the authors. The authors do not believe that intravascular hemolysis is responsible for the major portion of this red cell deficit because in many patients there was little or no staining of the plasma with free hemoglobin. They are of the opinion that the red cell deficit is due in the main to sludging or trapping of large masses of red blood cells in the capillaries in and adjoining the burned area. The hematocrit data do not necessarily indicate the extent of the anemia in burns especially when plasma and red cells are lost in disproportionate amounts into the burned area.

The general plan of a clinical experiment was to treat the patient a burn by pressure dressings and to give intravenous whole blood infusions of 500 to 1000 c.c. every 6 hours for the first 48 hours along with enough saline and other fluids to keep up a urinary output of from 50 to 100 c.c. per hour. Every effort was made to have the patient take fluids by mouth rather than by the intravenous route. Fluids were given in the form of water soft drinks, milk or fruit juices. For children of from 1 to 5 years of age, the six hourly infusions of whole blood were usually limited to from 150 to 300 c.c. in all burned patients every effort was made to give hemoglobin level above 100 per cent during the first 4 days of therapy. Penicillin usually 100000 units daily was given to all patients.

When burn patients were given plasma alone, even in large amounts, it was not unusual to find low plasma protein levels on the fourth or fifth day especially in cases in which the burn was deep and extensive. On the other hand in the series of burns treated with large amounts of whole blood the plasma protein levels were maintained at more nearly the optimum level. This may have been due to improved blood flow through the liver during the period of burn shock, and consequently less liver anoxia in the patients treated with whole blood. Stated differently one of the advantages of whole blood therapy may be the maintenance of the liver in such a state that plasma protein production is carried on in a more nearly normal manner during the initial burn period. The authors found it possible to maintain a good urinary output even when the impression appeared to be quite marked.

The authors have been pleased to note that with whole blood therapy there has been less "toxemia" than did others receiving plasma or whole blood. The authors have been pleased with the rapidity with which growth of epithelium has taken place in burned areas that at first appeared of a depth and extent to require extensive skin grafting. An increased incidence of thrombosis has been noted in patients with hemoconcentration has been noted, and one might hesitate to give whole blood in burn patients, but it is interesting to note that in the series of 33 patients, 29 of whom survived, there was no instance of thrombophlebitis or pulmonary embolism recognizable clinically.

JOSEPH K. NABAR M.D.

Ungley, G. C., Channell, G. D., and Richards, R. L.:
The Immersion Foot Syndrome. *Brit. J. Surg.*
1945 33 17

Prolonged exposure of the extremities to moist cold insufficient to cause tissue freezing produces the well defined syndrome of immersion foot. In the natural course of a typical case of immersion foot there are 4 stages: the period of exposure and the prehyperemic, hyperemic, and posthyperemic stages. During the first two stages the feet are cold numb swollen and pulseless, and pain is not a prominent symptom. Within a few hours after rescue the feet become hot and flushed and the pulses are full and bounding. With hyperemia comes pain which is severe, burning or throbbing in character and increases in intensity for from 24 to 36 hours. Swelling increases with the hyperemia, and there is a rapid recovery of sensation from above downward until from 7 to 10 days after rescue, when a relatively stationary sensory picture is obtained. Typically the sensory loss is of the "sock" or "carpet slipper" distribution. Further recovery of sensation is slow and is dependent upon the regrowth of nerve fibers. Areas that are to become gangrenous fail to warm, remain white or blue, and blister extensively. The duration of the hyperemic stage varies from a few days to months according to the severity of the case.

The posthyperemic stage may be absent in mild cases, but in the typical case it is first manifested by a change in temperature of the feet, which become cool on exposure to mild cold. The feet remain cool for several hours and later may become permanently cold and "cold-sensitive." In some cases the feet are also heat-sensitive. Spontaneous excessive sweating of the feet is a prominent feature of the posthyperemic stage, and recurrent swelling, tingling or shooting pain, and blistering are other complaints. In about two-thirds of patients with immersion foot the hands are also affected, usually less severely.

When a limb is immersed in cold water the temperature of the digits falls rapidly to within 1° to 2° of the water temperature. The earliest records of skin temperature in immersion foot syndrome have been made in from 9 to 12 hours after rescue. At this time the digits were already warm and within a few hours reached full vasodilation level. Once the hyperemic stage is fully developed the hand or foot, except for gangrenous areas, is warmer than the upper arm or thigh and the normal vasoconstrictor gradient is abolished. Reflex vasomotor activity in response to heat or cold is absent, but returns gradually. In the posthyperemic stage the feet are almost habitually cool, and many degrees of reflex vasomotor activity may be observed. In the more severe cases there is complete failure of reflex vasodilation.

In the experience of the authors, the most significant factor in prognosis is the amount of damage to the peripheral nerves. A useful criterion is the extent of loss of sensation to cotton wool touches at the end of the first week, and cases have been subdivided into 4 groups on this basis:

Grade A Minimal cases without interference with transient interference with nerve function.

Grade B Mild cases with reversible nerve damage.

Grade C Moderately severe cases with irreversible (degenerative) nerve lesions.

Grade D Severe cases with irreversible nerve lesions and gangrene.

The essential cause of immersion foot syndrome is prolonged exposure of the limbs to cold insufficient to freeze the tissues. Contributory factors are malnutrition and exhaustion, and the relative immobility and continued dependency of the feet. Mechanical interference with circulation as from tight clothing or shoes is a factor. Chilling of the upper part of the body from wind and wetness acts by reducing peripheral circulation. The disorder may arise in extremities exposed to prolonged cold with no more damp than is provided by condensed perspiration.

The difference between frostbite and immersion foot is important but is not always clear cut. In general, frostbite causes death of tissue by freezing, and skin, being most superficial, suffers most, in immersion foot there is prolonged chilling and ischemia, which affects the tissues with the lowest biological resistance, namely nerve and muscle, most severely. Even with irreversible nerve damage there may be no loss of skin.

In the series of patients observed by the authors there were two groups of survivors from shipwreck in warm waters. Edema of the feet may follow exposure in open boats, in the tropics. This group does not form a simple clinical entity. Many of the cases resemble the peripheral vasoneuropathy observed after chilling. A number of factors are probably involved such as immobility and dependency of the feet, immersion in warm sea water, semi-starvation, dehydration, and the effects of sunlight.

Pathological material obtained from tissues affected with immersion shows that nerve and muscle suffer most severely. The peripheral nerves undergo a process of patchy Wallerian degeneration. Changes are most marked in the distal portions of the nerves and fibers of small calibre appear to suffer more severely than large medullated fibers. The clinical and pathological evidence is in favor of the hypothesis that during exposure and in the prehyperemic stage intense vasoconstriction is the predominant feature. The combination of chilling and ischemia gives rise to a peripheral vasoneuropathy. The early hyperemic stage appears to be due to release of stable vasodilator substances in the tissues, and once the effect of these has subsided, the hyperemia is maintained because of paralysis of peripheral vasoconstrictor fibers. The late vascular phenomena are more difficult to explain but it is assumed that they are the result of denervation and the subsequent re-innervation of peripheral blood vessels, which may also acquire a sensitivity to cold analogous to that seen in the Raynaud syndrome.

In discussing the treatment of immersion foot, confusion has arisen because methods which are of

value in one stage have been wrongly employed in another. During the prehyperemic stage the authors advocate an intermediate course between cooling to 2 to 5°C as advocated by some and rapid warming to 37°C , as advocated by others. The degree of warmth applied should be no greater than that needed to permit relaxation of the arteries. While warming the body exposure of the extremities to a cool atmosphere (18° to 23°C) appears to be logical and satisfactory. It is emphasized that efforts to hasten the release of vasoconstriction, whether by body warming, local warmth sympathetic block, or drugs may do harm unless steps are taken to control the degree of vasodilation when it occurs. During the hyperemic stage several methods have been suggested to limit the excessive exudation that occurs. Too rapid return of circulation Treatment by cooling alone is often sufficient and should begin as soon as vasodilation develops. The optimum cutaneous temperature for prolonged cooling is 21°C . In the posthyperemic stage and for the late sequel of a cold-sensitive state and for the late sequel of a not only for the affected extremities but for the rest of the limbs and for the trunk. Smoking should be avoided if there is a tendency to vasospasm. Occupational therapy is of value. It is in this stage that sympathectomy or sympathetic block may prove of value in treatment.

JOHN L. LUNDQUIST M.D.

Blackburn, G., and Rob, C. G.: The Abdominal Wound in the Field. *Brit J Surg* 1945 33 46

The treatment of an abdominal wound commences immediately after wounding and resuscitation is very important. This usually consists of warmth and morphine but plasma has also been used in exceptional cases. Blood has saved many lives early to great advantage. Evacuation should be carried out with the transfusion running as a second resuscitation is far more difficult and lengthy than the first. A greater use of the "in ambulance transfusion" is desirable. The morphine is preferably given intravenously but will rarely be needed after the wounded man has reached the advanced surgical center. Here the amount of further resuscitation required is assessed, the guiding factors being the blood pressure, pulse rate, and state of the peripheral circulation. It should always be remembered of course that ether used as an anesthetic is a stimulant, and that the relatively slow pulse of the average thoracoabdominal wound will quicken dramatically when the pleura and peritoneum are opened. However the majority of these patients have lost blood which requires equivalent replacement (5 pints are usually sufficient) with plasma to follow as required. Immediate operation is undertaken only on account of continued hemorrhage, especially from the mesenteric vessels, gross associated muscle wounds or prolapsed and strangulated intestine.

In view of the high mortality of exploratory laparotomy in these injuries the author stresses the need of exact diagnosis and in this connection

emphasizes the importance of auscultation of the abdomen for the presence or absence of peristaltic sounds. Thus he adduces figures from his material showing that in the presence of lesions of the hollow viscera peristalsis was present in only 5 instances and absent in 84 while in the absence of hollow visceral lesions peristalsis was present in 64 instances and absent in only 1 instance. However, he believes that absence of borborygmi indicates thorough soiling of the general peritoneal cavity.

Röntgenography has been of little value in abdominal wounds, especially with the type of machine available in forward work. Of course it is apt to be of value in the case of associated injuries which the author believes to be of great importance even providing for their operative treatment either with or preceding the opening of the abdomen.

The authors do not believe that thoracoabdominal wounds are more grave than the purely abdominal variety but that in the presence of pelvic complications the results are apt to be poor. When the rectum is intact they favor the use of the Murphy drip because with the usual venoclysis there is the danger of pulmonary edema resulting from the excessive administration of fluid into the vein after operation.

When the large bowel is perforated the authors do not subscribe to the dictum that exteriorization of wounds of the colon, wherever located is the accepted practice or at least, functional exclusion by a proximal colostomy. Sixteen of the patients were treated by suture, with 5 deaths, and 57 by exteriorization, with 26 deaths. It is believed that routine exteriorization of the right side of the colon is even simpler and safer procedure. That suture is the case in wounds of the splenic flexure where mobilization is often difficult and productive of wounds of course, these statements refer to young vigorous soldier patients at least, none of the deaths from peritonitis in this series has followed suture of wounds of the large gut. In fact in 1 case the wound of the intraperitoneal portion of the rectum was closed by multiple perforations of the small bowel from the bowel and mesentery, severe bleeding some 18 inches of ileum, some 6 hours after wound ing yet 2 feet of the ileum were resected and the rectum was sutured (without colostomy) and the patient made a good recovery.

Naturally wounds of the small intestine are the most numerous but they are relatively less noxious than the usual associated injuries (if one excludes involvement of the liver, kidneys and spleen). In fact, perforations seem to do well with single layered sutures only in contrast to the large gut for which two layers are invariably employed. Drainage of the abdomen in these cases has little to recommend it because blood, rather than intestinal contents is usually found in the peritoneal cavity. It has been the authors practice to drain the laparotomy wound when there has been gross soiling and to drain the

peritoneum only when bile or feces in large quantity has contaminated it.

Kidney wounds are of less concern at the forward station so long as the pedicle is not too severely involved when the pedicle is involved a nephrectomy may sometimes be required because of persistent hematuria.

The patient must remain in the field dressing station or the casualty clearing station following laparotomy until his general condition warrants evacuation and the abdomen can be said to be fairly quiescent this usually involves 10 days or more. The danger of sitting patients up too soon after laparotomy should always be remembered. The value of sulfadiazine (6 gm daily) in intravenous drip has already been discussed and results, as yet unpublished show sulfadiazine to be superior to penicillin in combating peritonitis. In the immediate postoperative period gastric suction and morphine are useful morphine (gr $\frac{1}{4}$ every four hours) has always proved satisfactory as a sedative for the patient and his alimentary canal, and it can usually be discontinued as soon as the bowels act. This is rare before the fourth day, but it does not mean that an enema before this is always contraindicated. It may indeed be a helpful measure in a patient with an injury of the small gut whose large bowel was loaded at the time of operation. An enema may likewise be useful as a preliminary measure before a rectal drip is started.

As regards postoperative diet, it is, at first, fluid however, careful fluid charts have repeatedly shown that a pint or more of fluid per day is retained even with continuous suction. Nutrient fluids are therefore of use. Two hundred milligrams of ascorbic acid daily are given as well.

More than 50 per cent of the deaths occur from shock or hemorrhage within 48 hours. After this, the fate of the patient depends partly on the nature and multiplicity of his wounds and the interval between wounding and operation, the most important cause of death being pulmonary (bronchopneumonia, pulmonary edema and embolism). Silent distention of the abdomen occurs quite frequently, but when not due to peritonitis it has not proved fatal in this series. Fluids other than plasma and glucose-saline solution have been employed—hypertonic saline solution for thoracoabdominal wounds with severe laceration of the lung, alkal for the patient with threatened anuria (1 per cent or 4 per cent sodium bicarbonate) and blood for the anemia which so commonly becomes evident on the fifth to seventh day when dilution has followed the initial blood loss. Fresh blood, in this case is infinitely better than the stored variety.

In the 210 cases of the authors' material there was a mortality of 37 per cent, this figure closely paralleling that of other larger series quoted elsewhere. Disappointment in the results is most common in the first 24 hours after operation when the patient is described as dying of shock, and only an elucidation of this condition is likely (in the view of the

authors) to make an appreciable difference in the mortality of abdominal surgery in the field.

JOHN W. BRIDGEMAN, M.D.

De Waal, H. L. Wound Infection. *Edinburgh M J* 1945 52 375

A knowledge of the fundamental physiological and pathological aspects of wounds will aid any surgeon in his search for methods of promoting wound healing. He should work in close co operation with his colleagues, the bacteriologist, physiologist, and pathologist and should concern himself as much with the study of infecting organisms and their effect on tissues as with the surgery and bedside treatment of wounds. The method of collection of material from wounds for bacterial investigation and the results in a series of cases are outlined and appraised.

In both old and fresh wounds swabs should be taken both before and after saline lavation and surgical treatment. Prompt culture should be made for aerobic and anaerobic organisms in the respective swabs. Results from a series of 658 wounds so examined showed: (1) insignificant infection in fresh wounds from 0 to 5 hours after injury, (2) the presence of infection in fresh wounds similar to that found in old clinically infected wounds from 5 to 8 hours after injury, (3) infection by both bacteria and saprophytes in 88.8 per cent of the cases after 8 hours, (4) a decrease of organisms in fresh wounds after cleansing and surgery, (5) that clinically infected wounds already under treatment contained chiefly nonpathogens (6 and 7) a decrease in non-pathogens but a proportionate increase in tissue invaders particularly hemolytic streptococci, in the tissue swab after saline cleansing as compared to the findings in the swab taken before cleansing (comprehensive swab) and (8) that subculture from primary fluid cultures gives an erroneous idea of the proportions of organisms.

It is emphasized that it is the invading organisms on the spreading edge and in the deep tissues of a infected lesion which must be discovered and dealt with rather than the organisms in the pus on the surface. This necessitates the two swabs, the second one taken after the pus has been removed with meticulous regard for the delicate healing tissues. Bacteriological studies in these cases showed that the staphylococcus albus, saprophytes, and other organisms were proportionately more prevalent in swabs taken before lavage, while the hemolytic streptococcus was more prevalent in swabs taken after lavage, and the staphylococcus pyogenes was found in relatively the same proportions.

It is postulated from observations that the organisms in the deep tissues prepare the susceptible tissues for later invasion by less pathogenic but more numerous invaders the latter which are prevalent in the pus and tissue detritus have displaced the less hardy but more pathogenic organisms in the pus as plants are choked by weeds. Hence, the tissue below the pus is the important area to be swabbed if the all-important invading pathogens are to be

discovered and proper therapeutic methods carried out.

PHILIP B. CHAFF, M.D.

ANESTHESIA

Beecher H. K.: *Anesthesia for Men Wounded in Battle*. *Ann Surg* 1945 122 867

Progress in the field of anesthesia in the last 30 years has made possible many of the advances of surgery. The author in this article attempts to sift out the anesthesia procedures found to be practicable in warfare and necessary for the best military pentothal, which is admirably suited to wartime surgery has had its first significant trial in this war. The author discusses its use on the basis of the experiences in the Mediterranean Theater of Operations.

A number of factors are important in the choice of anesthetic agents. Simple durable equipment is essential because of the need for rapid mobilization. The problems of supply soon convince an anesthetist that the simplest agents such as ether, sodium pentothal, and procaine hydrochloride are adequate for the forward zone. Personnel problems are important also as shown by the fact that one third of the Theater's specialists in anesthesia had only three months or less of special training.

The preoperative preparation of patients has been frequently discussed elsewhere. The author believes seriously wounded men need little preanesthetic medication. Morphine is to be avoided except for the relief of severe pain, since with a poor peripheral circulation the morphine which has been previously administered may or may not have been absorbed from subcutaneous deposits and with re-ruscitation and later vasodilatation the morphine may be rapidly taken up into the blood and poisoning occur. Atropine is important to cut down secretions when ether and pentothal anesthesia are used. Intratracheal intubation under general anesthesia is desirable for intracranial manipulation, thoracic and abdominal surgery, and in cases in which the patient's position makes it difficult to maintain the airway. Or in which the operation exceeds an hour or so. The routine use of the bronchoscope is undesirable because the trachea can be kept clean by frequent aspirations with a catheter. The insertion of the bronchoscope requires prolonged deep anesthesia which is undesirable or deepening of the anesthesia with possible harm to the patient at the end of a trying operation. If topical anesthesia is used and the patient vomits on recovery from the general anesthetic, aspiration of the vomitus is almost certain.

Ethyl chloride and chloroform are little used and cyclopropane and ethylene have not been issued to the American Army in this theater. Nitrous oxide is useful for minor surgical procedures (painful dressing changes) to supplement other forms of anesthesia (sodium pentothal) and to induce ether anesthesia as the induction of ether is not unpleasant the use

of nitrous oxide is not indispensable. Ether is the choice for the seriously wounded. If surgery is to be undertaken in patients in shock or impending shock, ether is the best tolerated anesthetic agent. Ether provides practically all the anesthesia for major cases in field hospitals. It was used too little at first, but its use has increased in the surgically important group of wounds of the abdomen and thorax and in compound femur fractures.

In September 1943 deaths from sodium pentothal were so common that the question of abandoning this agent was raised. Two correctable factors were found present when the causes of these deaths were examined: (a) its frequent use by completely inexperienced individuals and (b) its use in cases in which it was contraindicated. The advantages of sodium pentothal—its compactness and simple equipment, the smoothness of induction, the prompt awakening of the patient, the infrequent unpleasant after effects and the number of cases in which an inexperienced man can get by with it—have led to the decision to continue its use and at the same time take measures to correct (a) and (b). The disadvantages of sodium pentothal are the facts that overdosage is often difficult to overcome, that its use is incompatible with certain types of injuries and that the fatal dosage varies widely in different individuals.

Pentothal destroys the sensitivity of the respiratory center to its normal stimulus carbon dioxide. To maintain respiration a shift is made from the normal driving action of carbon dioxide on the respiratory center to the action of anoxia on the chemoreceptors. Anoxia stimulates the carotid mechanisms in the neck. Anoxia stimulates respiration under full pentothal anesthesia as well as under light anesthesia. Interpreted and more pentothal has been given. When deaths have probably resulted. In operations exceeding one half hour oxygen should be administered with pentothal and then the character of the respiration is a helpful guide to the depth of anesthesia. The use of carbon dioxide to stimulate respiration depressed by pentothal is contraindicated because under such circumstances it causes depression.

The use of a 2.5 per cent solution of pentothal the routine administration of oxygen and frequent observations of the pulse and blood pressure constitute the acceptable practice in operations requiring ether is recommended if the operation requires more time. The preoperative use of morphine requires more than one half to three fourths of an hour. A shift to not be resorted to. It may cut down the total quantity of pentothal needed but the author suggests the supplemental use of 50 per cent oxygen and 50 per cent oxygen as a better means of accomplishing this end. Atropine in a dose of 1/300 gr one hour before operation and a dose of 1/300 gr given intravenously just prior to anesthesia is recommended to cut down vagal reflexes. If laryngeal spasm occurs 1/300 gr of atropine to be given intravenously is recommended.

Pentothal is contraindicated when (a) the patient is suffering from a morphine overdose, (b) when shock is present or anticipated, (c) when cervical inflammation is present (inflammation in the region of the carotid bodies and sinuses causes sensitization of the reflexes and may lead to sudden death) and (d) in the presence of gas gangrene (since these toxins produce severe circulatory damage).

The use of pentothal is usually unwise (a) when the operative position interferes with the airway (b) in intracranial surgery because the operations are long and bloody, and the pentothal may cause sudden respiratory depression and anoxia and (c) in severe burns.

Its chief use in military medicine has been in short procedures for which relaxation is not needed and the men are in good condition.

Local and regional anesthesia with procaine hydrochloride and topical anesthesia with pontocaine or cocaine have been used for neurosurgical, maxillo-facial, and minor surgical procedures.

Spinal anesthesia is usually a poor choice for recently wounded men, because their precarious circulation rapidly deteriorates under it. Its chief use is for emergency appendectomies and conditions unrelated to warfare.

Anesthesia was given in 15,925 cases, 1,628 (10.2%) being classified as abdominal injuries 150

(9.4%) as thoracic injuries with pleural involvement, and 508 (3.8%) as thoracoabdominal injuries.

Of the men listed in the files of this theater as specialists in anesthesia, only 10 per cent were certified by the Board, 20 per cent had only the anesthetic training of an internship, and 15 per cent had from one to three months of special training in anesthesia. The total number of physicians was so small that nurse anesthetists and a few corps men were used under close supervision.

Whenever possible the ablest anesthetists were assigned to combat zones as there the demands for native intelligence, judgment, resourcefulness, and technical ability are greatest. In some instances men of unusual ability were used to train anesthetists to be sent to forward areas.

By accepting the limitations of sodium pentothal, that is, avoiding its use in badly wounded men and for providing relaxation, and using it for short procedures in men in good condition a great reduction in the death rate which has been attributed to it has been possible. At the same time, its use has increased. Thus, sodium pentothal, together with ether and procaine, takes its place as one of the three most important anesthetic agents for use in military medicine and surgery.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Her L. G.: The Development of Roentgen Diagnosis. *Radiology* 1945 45 467

This article is an extensive concentrated review of the development of roentgen diagnosis. Special prominence is given to the role which contrast media played in further extending the applicability of this method. Two anatomical drawings of the human body display the organs made accessible to x-ray examination and give the name mode of administration, and the year that x-ray examination was first used for the diagnosis of disease of each of these organs. One plate shows contrast media denser than tissue, the other shows media which are less dense than the surrounding tissue. A bibliography of 326 references helps to establish historical priorities.

A table enumerates 44 groups of anatomical parts and disease processes to which roentgen diagnosis is particularly applicable. Several conditions in which x-ray diagnosis is of no avail are mentioned. Certain conditions can be diagnosed by other means at an earlier stage. In others the reverse is the case. The absence of roentgen findings may be significant in some conditions but meaningless in others and on the other hand the presence of x-ray findings may definitely indicate disease in some cases whereas in others they may not allow such conclusions. (Examples of each of these conditions are given.) The correct and incorrect use of the terms 'typical finding' and 'characteristic finding' is discussed. All these facts and problems show that only the correlation with clinical findings and the knowledge of disease aspects make it possible for one to arrive at the correct degree of emphasis with which a given x-ray finding should be appraised. As a general rule, a negative roentgen examination is much less significant than a positive one the most important exception being in chronic pulmonary tuberculosis.

As far as the future of roentgen diagnosis is concerned one may safely assume that practically no competing diagnostic procedure will replace this method. Usually the institution of other methods of examination, e.g., gastroscopy has given a further stimulus to roentgenology. The roentgen examination of the liver pancreas and spleen has not yet been perfected thus presents a inviting goal to the ambitious radiologist. Body time examinations at regular intervals, not only of the chest but also of the stomach (at least in cases with achlorhydria and a familial history of pernicious anemia) might lead further social importance till in its infancy. The detection of initial lesions is

Great progress in diagnostic roentgenology is to be expected when electronic image amplification will allow the production of incomparably brighter fluoroscopic pictures with negligibly small intensities of x-rays. Then motion and multiple projection studies will become a commonly used method and roentgen cinematography will no longer encounter its present difficulties. This may contribute to a shift of roentgenological interest from anatomical lesions to abnormalities in organ physiology and minor changes in the function of organs.

GRIFFITH S. SCHWARTZ M.D.

Arbuckle, R. K., Shelden C. H. and Pudenz, R. H.: Pantopaque Myelography: Correlation of the Roentgenological and Neurological Findings. *Radiology* 1945 45 355

The authors have analyzed 100 consecutive cases with a provisional clinical diagnosis of protruded intervertebral disc, all in naval personnel, of whom 87 were subjected to pantopaque myelography. Most of the men were between 20 and 30 years of age and 50 per cent of them had had symptoms for only 6 months or less and 70 per cent for not more than one year. The commonest types of trauma associated by the patient with onset of the symptoms were the lifting of heavy objects falls or slipping on wet surfaces without falling.

Preliminary filming of the lumbosacral area showed a list of the lumbar vertebrae either toward or away from the side of the lesion in 47 cases loss of the normal lumbar lordotic curve in 37 cases and narrowing of the intervertebral cartilage space in only 13 cases. However bony proliferation and narrowing of the cartilage space concerned were present, almost without exception in those patients who had had symptoms for over 3 years.

The injection of 3 c.c. of pantopaque in the lower lumbar region was done usually with the patient prone on the tilting fluoroscope. Defects even partial obliteration of an axillary pouch or slight elevation of a nerve sleeve were searched for both with oblique, cephalad and caudad, and spot films were made with the patient in the prone or even in the oblique position. Lateral views gave no additional information and were abandoned. At the conclusion of the examination, pantopaque was pooled at the tip of the needle and in 70 per cent of the patients about 50 per cent of the oil was removed. With experience the time for the whole myelographic procedure totaled 20 minutes. The authors observed no toxic manifestations or signs of root irritation and no more headache or signs of root irritation routine lumbar puncture was complained of than after an operation was performed in 13 cases of this series of 100 without myelography, in a group of 5 cases myelography was unsuccessful because of subdural injection. Among the 83 cases in which mye-

lography was performed after successful opaque injection, the procedure was diagnostic of two protruded discs in each of 3 patients diagnostic or questionably so of a single protruded disc in 53 cases of a disc and tumor in 1 case and of a tumor alone in 4 more cases—all proved at operation. Three more cases had clinical and myelographic evidence of protruded disc but were not operated upon another 2 had positive myelograms but were negative at operation 7 were negative at myelography but showed a protruded disc at operation, and 9 more which were negative myelographically were not operated upon. All but 1 of the 83 protruded discs found were caudal to the fourth lumbar vertebra whereas of the 5 tumors encountered 4 were above the fourth lumbar and below the eleventh dorsal vertebra.

The authors were concerned particularly with the group of 7 cases which were negative at myelography but revealed a protruded disk at operation, and found that all of these cases had a narrow subarachnoid space measuring 6 mm or less in diameter as did also the 10 cases in which myelography was only questionably positive. On the other hand, there was operative confirmation of the roentgen findings in all of the cases with a subarachnoid space wider than 16 mm. Even with a narrow subarachnoid space, midline or large posterolateral protrusion offered no myelographic difficulties. Failure to demonstrate the lesion occurred in patients having both a narrow subarachnoid space and a posterolateral protrusion too small to encroach either on the narrow column of pantopaque or on the adjacent nerve sleeve or pouch. No correlation existed between the interpedicular and subarachnoid widths.

The authors conclude (1) that roentgenograms of the lumbosacral spine without the aid of myelography are of little definite help in the diagnosis of protruded intervertebral discs (2) that pantopaque is a satisfactory medium for myelography because of the ample contrast, its lack of irritating properties, low viscosity, and ease of removal (3) that myelography should be carried out as an aid in diagnosis and localization of single or multiple protruded discs, and in differentiating them from tumors and (4) that a negative myelogram in a patient whose subarachnoid space measures less than 16 mm. does not preclude the presence of a protruded disc.

LILLIAN DONALDSON M.D.

Schnitzler M T and Booth G T: Pantopaque Myelography for Protruded Discs of the Lumbar Spine. *Radiology* 94:3, 45 370.

Pantopaque, a radiopaque mixture of isomeric ethyl esters having a provisional principle constituent of ethyl iodophenylundecylate, and containing 30.5 per cent of iodine in firm organic combination was used satisfactorily by the authors for diagnostic myelography in 100 patients of a total of 313 with low back pain who were admitted to the surgical service of Bushnell General Hospital, Brigham City Utah.

Thirty of these 100 cases showed myelographic evidence of protruded intervertebral disc, multiple in 3 patients, which was verified at operation. Another 5 cases, negative at myelography showed protruded discs at operation, and 2 cases positive myelographically proved negative at operation. These 2 "false positives" occurred early in the series and the visualized defect reported at first as evidence of an extradural mass, was on review found to be due to the needles being left in place at the time of myelography an error of interpretation which was later avoided. Thirty-seven was the total number of patients operated upon. A review of the premyelographic roentgenograms of the lumbar spine in the 35 cases in which a protruded disc was found at operation showed a definite narrowing of the intervertebral disc in only 7 cases.

The technique of the procedure is recorded in detail. In more than 80 per cent of the cases subjected to pantopaque myelography, over 80 per cent of the injected oil was removed at the end of the procedure. The authors stress the desirability of avoiding the suspected site of lesion as the site of injection because injection and subsequent removal may be more difficult, the needle may strike the lesion and enhance or distort it, or the needle itself may create a defect as reported.

A reaction occurred in 3 cases in this series of 100, manifested by symptoms of meningismus and elevation of the cell count, and in 2 instances by increase in the total protein in the spinal fluid, but rapid recovery occurred without sequelae. The degree of reaction, as gauged by changes in the spinal fluid, was not directly proportional to the amount of oil retained.

The authors conclude that the verification of the presence of a protruded intervertebral disc or other intraspinal lesion and the accurate localization and occasional demonstration of a multiplicity of the lesions make the use of myelography with pantopaque (which they prefer to air or lipiodol) advisable in indeterminate cases of low back pain with acute

LILLIAN DONALDSON, M.D.

Gershon-Cohen J: Internal Derangements of the Knee Joint; The Diagnostic Scope of Soft Tissue Roentgen Examinations and the Vacuum Technique Demonstration of the Menisci. *J. Resid.* 1945, 54 338.

The value of the roentgen examination of the soft tissues and menisci of the knee has repeatedly been stressed.

It is not necessary to resort to special techniques. The addition to the routine examination of the knee in the anteroposterior and lateral views of the longitudinal view of the patella and of bilateral views of the menisci will suffice. If any abnormal findings are disclosed, further oblique and so-called lateral condylar views may be supplemented.

It is important that for the viewing of each roentgenogram one be supplied with a source of light which has wide variable intensities and that the

field of illumination can be regulated in size and shape for optimum visualization of the soft structure outlines.

The technique employed by the author for bilateral anteroposterior views of the meniscus is briefly described. In the interpretation of the findings, no significance is attached to irregular margins or defects of the meniscus since they may occur under normal conditions. Only the nonvisualization of the meniscus carries diagnostic weight because demonstration of the meniscus is impossible. It must be mentioned however that even with the best techniques, the internal meniscus can be demonstrated in not more than 80 per cent and the external meniscus in not more than 30 per cent of all the cases. If therefore the meniscus cannot be demonstrated in either knee joint it is presumed that the patient falls into the small 20 per cent group in which the internal meniscus cannot be demonstrated and thus the findings have no clinical value.

The finding of slight excess synovial fluid in an acutely injured knee evidenced by a failure to demonstrate the meniscus suggests abnormal changes especially if the opposite side appears normal. There may be an actual fracture or loosening of the attachment of a meniscus or a swelling of the tibial collateral ligament resulting from a sprain. Occasionally the demonstration of the meniscus in a swollen knee will indicate absence of excess synovial fluid, and suggest a periarthritic rather than an intra articular swelling.

The author discusses in detail the clinical symptoms and the significance of the roentgen findings by the above method in internal derangement of the knee joint: loose bodies, sprain or rupture of the tibial collateral ligament, periarthritic bursitis of the meniscus, and neoplasms. Typical roentgenograms are used for the purpose of illustration. The conclusion is reached that the roentgen study of the soft tissues of the knee in conjunction with examination of the meniscus is of definite practical value.

Garland, L. H.: X Ray Burns from Fluoroscopic of the Gastrointestinal Tract. *J Am Med Ass.* 1945 129: 419.

Knowledge of the effects of x rays on the patient is not kept pace with the increased roentgenological work done in both military and industrial hospitals. The newer machines may be even more dangerous than the nonhomologous. Since the intensity of x-rays varies inversely with the square of the distance, the nearer the tube is to the patient the greater the possibility of skin damage. For adequate protection, the following factors should be borne in mind: adequate distance, reason-able voltage, low milliamperage, small fluoroscopic field and as minimal fluoroscopic examination time as possible. The latter applies especially to the manipulation of fractures under fluoroscopic control for long periods of time. Such procedure frequently

results in permanent skin damage both to the patient and doctor.

Four cases of x ray burns that resulted from prolonged exposure during the course of gastrointestinal examinations are reported. The author stresses the point that x ray burns resulting unnecessarily from fluoroscopy can be avoided by using a safe distance between the tube and the patient (from 12 to 18 inches), 1 mm. of aluminum filter (from 12 to 18 inches), a beam size not larger than 6 square inches, no more than 3 minutes of exposure per examination, and no more than 4 such examinations per month. Above all proper adaptation (at least 10 minutes) of the examiner's eyes is essential in fluoroscopic work.

MAURICE D. SACCS, M.D.
Pelice, C. B., Cone W. Y., Elridge, A. E., and Tyso J. G.: Roentgen Therapy of Primary Neoplasms of the Brain and Brain Stem. *Radology* 1945 45: 247.

The authors treated between January 1, 1939 and December 31, 1943 a series of 91 cases of primary malignant neoplasms of the central nervous system by roentgen therapy. Of these 60 cases have been followed up and 25 patients were found to be either alive and well or alive and well save for residual symptoms.

In the beginning a more conservative procedure was used consisting of from 3,000 to 6,000 r (in air) which were dividing over multiple ports and given in several series at 3 month intervals but later the total dose was raised from 10,000 to 15,000 r (in air). The factors employed were roentgen rays of 2.0 mm of copper high voltage layer with Thorax filter at 50 cm. focal skin distance. The initial dose was 100 r per day to each of two fields. If no significant

TABLE I — THE SURVIVAL RATE IN RELATION TO THE TUMOR DOSE

Type of tumor	Postoperative, postirradiation survival	Maximum dose in roentgens	Minimum dose in roentgens	Average dose in roentgens
Glioblastoma multiforme 5 patients alive	0-47 mo. Average 7 mo.	—	—	—
20 patients dead	—	—	—	—
Astrocytoma 3 patients alive	6-41 mo. Average 24.3 mo.	3,600	6,300	9,750
8 patients dead	—	—	—	—
Astroblastoma patient alive	6-41 mo. Average 7 mo.	14,800	6,300	8,400
patient dead	—	—	—	—
Ependymoma patients alive	2.3 mo. 6 mo.	—	—	—
patient dead	—	—	—	—
17-40 mo. Average 28.5 mo.	7,300	6,850	7,400	—
9 mo.	—	—	—	—

TABLE II — SURVIVAL AS RELATED TO THE TYPE OF TUMOR

Type of tumor	No. of cases	Postoperative and postirradiation survival		
		Alive—years	Alive—months	Average
(A) Glioblastoma multiforme				
Alive and well		47 mo	3 mo	8.5 mo
Alive with residual symptoms		—	—	11 mo
Alive with marked symptoms		—	—	47 mo
Dead	30	8.4 mo	mo	14.5 mo
(B) Astrocytoma				
Alive and well		64 mo	mo	44.6 mo
Alive with residual symptoms	3	—	—	46 mo
Dead	6	44 mo	mo	7 mo
Anaplastic				
Alive and moderately well		—	—	34 mo
Dead		—	—	6 mo
(C) Ependymoma				
Alive and well		40 mo	7 mo	28.5 mo
Dead		—	—	9 mo
Meningioblastoma				
Alive and well	3	40 mo	13 mo	27 mo
Alive with residual symptoms		—	—	36 mo
Dead	3	7 mo	6 mo	6.6 mo

reaction developed within from 8 to 10 days the dose was increased to 150 r per field. The tumor dose approximated 90 per cent of the total roentgens in air for the frontal lobe lesions 83 per cent for the temporal and parietal lesions and 71 per cent (76.5 per cent for children) for the occipital lesions. The survival rate in relation to the tumor dose is shown in Table I.

The scalp tolerated the amount of radiation given very well. Regrowth of hair has been excellent even after 15,000 r.

The mental state likewise improved considerably co-ordination returned, and, although some aphasia or ataxia remained the mind cleared. In not a few of the cases the formerly-held responsible positions in society could be resumed.

The survival period depended to a certain extent on the type of tumor. This is shown in Table II.

As may be seen, glioblastoma multiforme had an almost reciprocally low proportion of survivors as compared with astrocytoma. Tumor doses in excess of 7,500 r will be required.

As a whole, definite clinical improvement was effected by roentgen therapy of the malignant primary neoplasms of the brain and brain stem. No late degenerative changes have been observed which could be attributed to the irradiation.

T. LECURIA, M.D.

Fairchild, G. C., and Shorter, A.: Direct Irradiation of Cancer of the Stomach and Other Viscera Exposed Temporarily at Operation. *Lancet*, Lond., 1945 249: 58.

The authors report that the end-results of carcinoma of the stomach are poor. In their experience, the percentage of 5 year cures has been from 1 to 10 per cent and they believe that in most instances failure is due to (1) late diagnosis of lesions that are inoperable, (2) incomplete surgery and (3) irradiation. Results with external irradiation have been poor because of the necessity of avoiding injury of neighboring organs and the radioresistance of gastric tumors. Contact therapy covers small areas, at a depth of more than 1 cm., with little effect. Unequal distribution of irradiation is one of the faults of radon and implantation. The use of intracavitary irradiation, as advocated by Livingston and Puck, has been limited because of the fact that the tolerance dose has not been established.

In view of the poor results which have been obtained in the treatment of gastric carcinoma, a new approach—direct irradiation at the time of surgery—to improve the percentage of 5 year cures, was deemed feasible. The advantage of this method is that neighboring organs are protected, also, the tumor dose may be high because radiation therapy will not be worried by skin effects such as are seen following external irradiation.

The authors used this method of irradiation not only on gastric lesions but also on cancers of the esophagus and of the colon. In all instances there was at the time of surgery, consultation between the surgeon, the radiation therapist, the pathologist, and the anesthetist as to the best form of therapy. In radiation therapy, 5 units were used simultaneously (one anteroposteriorly, directly to the lesion, and the other posteroanteriorly through the skin to the lesion). Earlier in the series, only 1 unit was used. It was believed that with 5 units a greater and more effective tumor dose could be delivered at one time and that it would not be necessary to give supplementary external irradiation, as had been required when only 1 unit of radiation therapy was used.

Fifteen patients were treated in the manner reported viz., 9 with cancer of the stomach, 3 with cancer of the esophagus, 2 with cancer of the colon, and 1 with cancer of the pancreas. The tumor dose was 1,300 roentgens. Of the 15 cases, 6 were palliative. No unusual postoperative radiation complication has been observed.

The authors are of the opinion that this method is of value and that it is a reasonable approach to the problem of visceral carcinoma.

MAURICE D. SACKS, M.D.

Golin, L. S., and Hoffman, E. F.: Contact Roentgen Therapy in Cancer of the Bladder. *Am. J. Roentg.* 1945, 54: 392.

The authors have now modified the method of treatment of carcinoma of the bladder on which they reported in 1940 and which consisted in marsupialization

tion of the bladder with subsequent contact irradiation of the tumor by low voltage roentgen rays and are using instead suprapubic cystostomy under spinal anesthesia and reduction of the tumor to its base by fulguration, followed by direct irradiation of the tumor with one or two reopenings of the bladder for further irradiation.

The apparatus employed is a Philips-Metalix operating at 50 kv., constant potential, and 3 ms. with a shock proof tube 23 inches long and slightly less than 2 inches in diameter at its active end. The anode is 2 cm. from the surface of the tube and the roentgen afflux is 1.543 per minute with a filter of 1 mm. of aluminum. This construction permits easy introduction of the tube, encased in a sterile stock inette and rubber sheath, through the cystostomy wound. The target surface distance used is 22 mm. and a first dose of 5,000 r. in air is administered to the base of the tumor. Most cases treated have had two cystostomies about 1 week apart, and have received a total dose of 10,000 r. Only moderate sloughing followed the treatments and no severe hemorrhage, perforation or fistula formation resulted, nor was there any primary mortality.

Treatment was limited to tumors not more than 3 cm. in diameter involving the trigone of the bladder since the alternative in trigone tumors is total cystectomy with its high primary and secondary mortality. The 3 cm. limit is considered important since greater size of the tumor would necessitate the use of several circular fields with either resultant dosage overlap or failure to include some small irregular areas in the treatment. For neoplasm of the vault or lateral walls of the bladder the authors prefer local resection if possible. They rationalize the use of this combined surgical and radiation procedure as follows:

Cancer of the bladder tends to metastasize rather late in its course and is often fairly radiosensitive and by contact irradiation a large dose can be administered to the tumor base without irreparable injury to the adjacent tissues. It is estimated that with a circular field 3 cm. in diameter and factors the same as specified previously the dose at a depth of 1 cm. is only 32 per cent of the surface dose, and at 4 cm. only 3.6 per cent.

The authors treated a series of 31 trigone tumors in this manner of which 13 were papillary and 18 infiltrating carcinomas, ranging from grades 1 to 4 with grade 3 predominating. The first 4 cases were subjected to marsupialization and received 10 or 11 treatments each at weekly intervals up to a maximum of about 28,000 r. in air in 22 days. The other cases were subjected to cystostomy and of these 15 received about 10,000 r. and some of the others less the minimum being 5,148 r. which were received in a single treatment. In addition to the original biopsy, a second biopsy was done in 20 cases at the final treatment and no cancer cells were found in 13 of these.

A survey of the results of this 5 year study showed 10 patients dead of cancer 9 of them within the

first year of treatment and 1 after 4 years. Two others are dead but they presented no evidence of cancer at postmortem examination. Of the 19 survivors 3 have so far lived 5 years another 3 for four years 5 have lived 3 years, and the rest from 1 to 2 years.

The authors have compared their results with those obtained elsewhere by total cystectomy radon seed implantation, and high voltage external irradiation and believe them to be at least as good as those obtained so far by these other methods. Further in view of the low primary and secondary mortality in their series they consider the method of contact irradiation preferable to total cystectomy for trigone tumors.

LILLIAN DONALDSON M.D.

Borak, J. and Taylor H. K.: Beneficial Effects of Roentgen Therapy in Advanced Cases of Rheumatoid Arthritis; Preliminary Report. *Radiology* 1945 45 377

A number of investigators have reported favorable results from roentgen therapy of various forms of arthritis such as gonorrheal arthritis, tuberculosis, gout, osteoarthritis and hypertrophic spondylarthritis. However in the rheumatoid (atrophic, proliferative) type of arthritis roentgen therapy has been regarded as less satisfactory.

The authors have again studied this subject and during the past two years have treated 60 patients with advanced rheumatoid arthritis by means of roentgen rays. These patients had failed to respond to the usually accepted methods of gold therapy, vaccines, physiotherapy, surgery, or any other method. Ten patients, with a total of 85 joints affected, were selected for a critical study. The cases are tabularly arranged attention being given to the following factors: age, sex, duration of the disease in years previous therapy, present roentgen therapy (joints involved, stage and dose) and the results obtained.

Rheumatoid arthritis is divided—mainly on the basis of the degree of impairment of the mobility—into 3 stages: first stage, in which pain and soft tissue swelling restrict the active mobility of the joint although passively it can be moved through its full range; second stage, in which the mobility is restricted both actively and passively to a varying degree; and third stage in which there is no motion at all.

Roentgenographically, in the first stage the joint space is normal although there may be a swelling of the periarthritic tissues and some decalcification of the bones. In the second stage there is usually a narrowing of the joint space, and sometimes destruction of the subchondral adjacent bone and in the third stage there may be complete ankylosis.

Pathologically in the first stage the cartilage may appear nearly or quite normal and the only visible change may be in the synovial membrane. The second stage is characterized by the formation of granulomatous tissue and the third stage is marked by destruction of the cartilages and their replacement

either by fibrotic strands or osteoid tissue until complete ankylosis results.

The roentgen dose is gauged as follows: for inflammatory edema, from 50 to 100 r in 1 session; for chronic inflammation, from 200 to 300 r in 1 to 3 sessions; for hyperplasia, from 800 to 1,200 r in about 3 weeks; and for granulomatous tissue, from 1,200 to 1,600 r in about 3 weeks. In the series mentioned the majority of patients received from 800 to 1,600 r. The factors were: 200 kv., 0.5 mm. of copper plus 1.0 mm. of aluminum, 20 ma., 50 cm. distance, H.V.L. of 0.9 mm. of aluminum. Each port was treated three times a week, some joints being cross-fired through 2 or 3 ports at each session. In multiple joints two joints were treated alternately so that treatment was given daily.

The results were good in most cases. Relief of the local symptoms, alleviation of pain, and even some increase in mobility were noted.

MISCELLANEOUS

Hinkel, C. L.: The Entrance of Pantopaque Into the Venous System during Myelography. *Am. J. Roentg.* 1945 54: 230.

Pantopaque used as a contrast medium in myelography is a valuable diagnostic aid. It contains 30.5

per cent iodine and up to the present has given rise to no complications.

A case is reported wherein some of this substance was seen entering the neighboring venous system during the course of myelography. A complete survey of the body over a 2 month period failed to reveal any evidence of dye or any other abnormality. The patient showed a low grade temperature of 99.4 F with a 13,000 white count for the next two days, which subsided on the third day. Urine examination within the first 24 hours showed 564 mgm. of iodine in 1,100 c.c. of urine. Re-examination of the urine two weeks later showed a trace of iodine.

Pantopaque is not intended for intravenous use, and up to the present time no case of this kind has been reported. This case was reported as a curiosity rather than as a complication. Little is known of the hydrolysis, breakdown, and excretion of pantopaque. Studies are still being made by many investigators.

How the medium got into the venous system is not clear to the author. It is thought that the vessel may have been injured by the spinal needle and when the patient coughed during the normal course of examination, the wall of the vein ruptured and the dye entered the vein. At all times, manifestations of toxicity were slight and there was no evidence of embolism.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Albaugh, C. H.: Congenital Anomalies following Maternal Rubella. *J Am M Ass* 1945 129 719

The author reviews the reports of Gregg, Reese, Swan and others on the occurrence of congenital defects following maternal rubella and reports an additional 9 collected and personal cases.

Of the 9 cases studied by the author 7 of the mothers had rubella, 1 morbilli, and 1 was exposed to morbilli. All of these cases occurred within the first 10 weeks of pregnancy and 4 occurred in the first 4 weeks.

Eight of the 9 infants had bilateral congenital cataracts and in 7 the pupillary reactions to light were poor. Strabismus was noted in 7 cases and nystagmoid movements in 4. No glaucoma was noted. Eight of the infants had congenital heart defects and 4 of these showed evidence of cyanosis. Two infants died of cardiac failure. Five of the infants had definite microcephaly and 3 were recorded as uncertain cases. Retarded development was noted in all cases, and 7 were considered feeding problems.

The author concludes that available data would suggest that 100 per cent of the mothers who contract rubella in the first two months and approximately 50 per cent of those who have rubella in the third month will give birth to infants with congenital abnormalities. The most common lesions are congenital cataracts, cardiac defects, deaf mutism and microcephaly. Poor development of the infants and feeding problems are common.

ORLAND B. SCOTT, M.D.

Walsh, F. M. R.: "Acroparesthesia" and So-Called "Neuritis of Women's Hands and Arms." *Brist M J* 1945 2: 596.

A syndrome found chiefly in women and characterized by numbness, tingling and uselessness of the hands and fingers is described and its etiology and treatment are discussed. It generally is seen in two groups of women: (1) middle-aged or elderly women who especially in wartime have had to carry a unwanted manual effort, and (2) younger women who are burdened by childbirth in addition to factory or house work. Factors common to all cases are fatigue and debility and the heavy use of the hands and arms. Symptoms begin gradually, attain maximum severity after some weeks or months, and thereafter fluctuate in severity according to the condition of the patient and treatment. They consist of paresthesias most severe on arising, waning during the day's work but increasing in the evening, often to the extent that they awaken the patient during the night. Positioning of the arms may offer temporary relief. These subjective symptoms predominate

although certain objective signs such as chronic fatigue, atonic musculature, low-set shoulder girdles and a rare obliteration of the radial pulse on traction of the dependent arm suggest the syndrome. Rest alone gives permanent relief; such measures as vitamin therapy, physiotherapy, estrogens or thyroid extract are superfluous.

The etiology is thought to be mechanical, in the altered topographical relationship between the shoulder girdle and the normal upper thoracic outlet. The lower components of the brachial plexus and on occasion the subclavian artery are compressed between the first rib and the clavicle which acts under the general atony of the muscles supporting the shoulder girdle. Pressure syndromes associated with a rudimentary seventh cervical rib or an abnormal scalenus anticus muscle should of course be ruled out; however these syndromes are usually unilateral and present more evidence of vascular disturbances in the arm than the less severe normal pressure syndrome of the first rib which is here described. No relationship has been found between the syndrome and pregnancy per se.

Rest in bed or the simple cessation of manual work produces appreciable relief and final disappearance of the symptoms. Initially a week in bed and a sedentary position during the day with the arms in slings, effectively brings relief to the patients. Abstinence from heavy work, with the arms supported in slings for a longer period when possible, together with shoulder massage and general tonic treatment, tends to prevent recurrence. Analgesics may be used as an adjunct.

PHILIP B. CHASE, M.D.

Corcoran, A. C., and Page, I. H.: Post Traumatic Renal Injury: Summary of Experimental Observations. *Arch. Surg.* 1945 51: 93.

The nature and treatment of post traumatic renal injuries were studied experimentally by means of investigations of the renal function in the following states: (1) hemorrhagic shock, (2) tourniquet shock and (3) simulation of the crush syndrome.

Shock due to hemorrhage was produced in dogs by repeated severe bleeding and transfusion. The shock due to prolonged or repeated bleeding is believed to cause a depression of the renal function by causing a vasoconstrictive ischemia which is not released by the transfusion of blood and restoration to normal of the arterial pressure. The persistence of renal ischemia and anoxia in experimental shock due to bleeding seems to explain the prolonged depression of renal function which may follow bleeding in human beings. Therapeutically it is significant that renal denervation does not prevent the vasoconstriction; hence, there is no experimental basis for the treatment of posthemorrhagic urinary suppression by spinal anesthesia or paravertebral block.

The nature of the abnormality makes the use of vasoconstrictor drugs illogical.

To study the conditions of crush syndrome, the renal function in dogs was observed during the onset of shock resulting from the experimental application of tourniquets partially occluding the arterial inflow. Renal vasoconstriction develops more rapidly and more severely during the onset of shock due to skeletal trauma than in shock due to bleeding in which tissue damage is milder and more diffuse.

The severe renal damage of the crush syndrome seems to depend on the combination of renal damage from trauma and that caused by muscle pigment. Both post traumatic renal ischemia and myoglobinuria were then produced in rats by the application of a tourniquet and the injection of myoglobin. Dogs were not satisfactory for this experiment as trauma severe enough to cause severe renal ischemia was followed by death within 24 hours, whereas minor trauma was followed by recovery. Renal damage is apparently produced by a combination of vasoconstrictive ischemia, oliguria, and aciduria, with deposition in the kidneys of muscle pigment or myoglobin.

In applying these principles to treatment, the prevention of the deposition of pigment is accomplished by reversing the conditions of oliguria and aciduria, which favor it. The treatment of shock by transfusions and pressure bandages inhibits the renal vasoconstriction on which oliguria may depend. A free flow of urine may occur during the re-establishment of blood volume by transfusion, and when this is not achieved or maintained gelatin may be added to an infusion of sodium lactate containing calcium lactate, since gelatin is itself mildly diuretic. A small dose of another diuretic such as sodium sulfate may be given. However the dangers and the ineffectiveness of alkalinization by the injection of citrate as the sole means of treatment are pointed out. LUCIAN J. FROST, M.D.

Abbott, W. E., Filling, M. A., Griffin, G. E., Hirschfeld, J. W., and Meyer, F. L.: Metabolic Alterations following Thermal Burns. *Ann. Surg.* 94:5 678.

In recent years there has been some controversy concerning the best means of combating shock in severely burned patients. Although there are a number of methods which apparently suffice to tide patients over the critical 48 hour period following an injury, their influence on the subsequent course of the patients is not well understood.

The authors compared a group of patients who were treated with plasma with another group who received whole blood intravenously and an electrolyte solution orally. The changes observed in various blood constituents and in the elimination of water and salt were recorded.

From the work presented and previous experimental work the authors draw the conclusion that the giving of whole blood early prevents or alleviates the anemia which occurs so commonly during

convalescence from a burn. Previous observations demonstrated the fact that a state of overhydration may in some instances, contribute to a decrease in the hematocrit, and also in the plasma protein concentration.

Patients with a severe or moderate burn accumulate large amounts of fluid in the traumatized area regardless of the type of therapy employed to combat shock, but it has seemed that the edema diminished more rapidly when salt solutions were used than when large amounts of plasma were administered. When plasma is given much additional protein is provided, but there is no evidence to show that the plasma protein in itself is of more than temporary value in these burned patients. In some of the authors' patients who received large amounts of plasma, low protein values were encountered, and in 3 of the severely burned patients these low values persisted until death. There is no reason to suspect that the giving of whole blood would be more beneficial than plasma for the prevention of hypoproteinemia, but the evidence indicates that the giving of plasma does not prevent the decrease in the plasma protein concentration.

It has been generally believed that by increasing the blood osmotic pressure by the addition of plasma proteins, especially albumin, shock could be prevented or corrected. In peripheral circulatory collapse resulting from a burn, however, the plasma is rapidly lost. Thus, most of the osmotic effect of albumin or of the entire plasma proteins is transient and when it is lost through the capillary walls into the injured area it must continue to exert an osmotic pull toward the injured tissues because of the protein which has then accumulated in that region. Since much of the administered protein is lost in patients in shock resulting from a burn, it would seem as though the best treatment would be (a) to give a substance which exerted an osmotic effect and would not be lost, (b) to render the injured capillaries less permeable, if this is possible, or (c) to increase the tissue tension to a point at which fluid would no longer tend to leave the capillaries in excessive amounts.

Apparently there is a substance derived from the surface of fresh plasma which has a coating effect and therefore tends to decrease the respiratory permeability. Therefore, it would appear as though whole blood or plasma would have some advantage over a salt solution alone, but since capillary permeability cannot be quickly or completely restored to normal, it would seem logical to give an electrolyte solution so that tissue tension would be increased.

From the results presented by the authors it can be seen that wide differences were found in the hematocrit readings during the period of shock, which could not be correlated with the extent and depth of the burn. The hematocrit, therefore, is frequently a poor guide to the type and amount of treatment that is necessary, especially since it is influenced by a pre-existing anemia, and the rate and number of cells destroyed or trapped from the

general circulation at and following the time of injury and because the normal hematocrit varies quite widely.

In the treatment for the first 48 hours it seems logical to give approximately 50 c.c. of blood to adult patients for every per cent the body surface is burned, or to give blood in amounts equal to from 1 to 3 per cent of the patient's body weight in kilograms. In employing the electrolyte solution it seems desirable to give a slightly hypotonic solution (from two-thirds to three-quarters strength) in order to increase the rate of urine excretion and in amounts equaling from 10 to 15 per cent of the patient's body weight during the first two days following the burn. Since there has been little experience with this form of treatment no absolute rules should be employed, but the treatment should be modified according to the severity and the degree of the burn and the size and response of the patient. When shock is not severe treatment may be given relatively slowly but if the patient shows evidence of peripheral vascular collapse therapy should be carried out rapidly until the condition has improved and urine is being excreted. It should be remembered that the larger quantities advocated are comparable to giving amounts of fluid which are roughly equal to an individual's total extracellular fluid volume (plasma and interstitial fluid volume), hence, when such amounts are employed additional liquids and foods should not be given or should be permitted only in small quantities for the first two days, as this would lead to an excessive fluid intake. If it seems desirable, dextrose can be added to the fluid to provide calories or some form of protein could be added to the electrolyte solution. In severely burned patients it has seemed that high caloric and protein intakes are better avoided initially. The authors usually give from 800 to 1,000 calories in the form of dextrin maltose daily for the first several days which supplements the vitamin intake by from two to five times the normal daily requirement.

In most of the patients excessive hemoconcentration was not encountered when whole blood was given provided an adequate amount of salt solution was employed.

When the hematocrit is definitely elevated (from 55 to 60 or more) the patient's blood pressure is low and little urine is being excreted, the authors see no reason that plasma should not be given instead of whole blood if it seems to be desirable. By the addition of red cells more oxygen might be carried to the tissues and, hence, anoxia prevented but it probably is not wise to increase the proportion of cells too much or the beneficial effect will be overcome because of stasis and a slowing of the circulation. Therefore if hemoconcentration is not excessive it probably would be preferable to give whole blood intravenously and an electrolyte solution orally but if the hematocrit rises to 60 or above plasma or a concentrated albumin solution should be temporarily substituted for blood. JOSEPH K. NARAT M.D.

Rislin H. and Thompson K. J.: Structural Changes in Early Filariasis. *Arch Pathol Chic.* 1945 40 320.

The present report is based on a study of 30 cases of early filariasis. An eosinophilia of from 6 to 11 per cent was found in 60 per cent of the cases. In the majority of the patients painful enlargement of the superficial lymph nodes of the arm or leg was the first physical sign. In 40 per cent of the cases the genitalia and the lower extremity were involved in a brawny edematous lymphangitis or an acute epididymofuniculitis. In 30 per cent both the upper and lower extremities were involved in the disease process.

Biopsy of the lymph nodes showed the presence of the filaria (*Wuchereria bancrofti*) in 20 per cent of the slides while in the other 80 per cent the histology was characteristic of filariasis but the organism was not shown.

During the early stage of invasion, the lymph nodes exhibited extensive hyperplasia of the primary and secondary lymph follicles and eosinophilic infiltration. The lymphatic vessels contained a pink like albuminoid fluid characterized as fluid lakes. The entire histological picture was in conformity with that of an acute systemic allergic reaction with manifestations of eosinophilia, edema, and hyperplasia. The subacute and chronic phases of the disease were characterized by an epithelioid cell endolymphangitis and perilymphangitis culminating in a typical granulation tissue reaction and finally fibroblastic proliferation.

Elephantiasis occurred only in those cases in which secondary streptococcal invasion took place. BENJAMIN G. P. SHARROFF M.D.

Roth G. M. and Kvale W. F.: A Tentative Test for Pheochromocytoma. *Am. J. Med. Sc.* 1945 210 653.

Paroxysmal hypertension and associated symptoms characteristic of the clinical syndrome caused by pheochromocytoma have frequently been described but the differentiation from such clinical conditions as coronary occlusion, hyperthyroidism, histamine cephalgia, migraine, menopausal and anxiety states, and persistent hypertension may be difficult. The most confusing cases are those of the hyperreactors and those in which the patients have essential hypertension with extremely labile blood pressure. In the past the diagnosis of suspected pheochromocytoma was confirmed by the attack which characterized this clinical entity. These attacks were precipitated by various means including physical exertion, change in position, massage of the abdomen on the side of the tumor, immersion of the extremities in cold water or the administration of insulin or of epinephrine. Since none of these methods of inducing attacks is dependable the authors believed that a simple procedure which would induce attacks at will would be of great help in diagnosis. They review the literature dealing with the subject and then give the results

of their own tests in the hunt for a simple procedure which might be used in diagnosing patients with tumors of this sort. Their results are summarized as follows:

An intravenous injection of 0.025 mgm. or 0.05 mgm. of histamine base was given to 51 persons, who were divided into four groups as follows: group 1, normal persons whose ages ranged from 20 to 48 years; group 2, hyperreactors to the cold pressor test whose ages ranged from 19 to 50 years; group 3, patients who had well established hypertension and whose ages ranged from 35 to 63 years; and group 4, patients suspected of having pheochromocytoma whose ages ranged from 39 to 50 years.

In the first three groups the blood pressure rose to a level somewhat less than the elevation obtained by the cold pressor test. Except for flushing of the face with subsequent headache, which was most intense in the patients with severest hypertension and pronounced tachycardia, no other symptoms were present. The results of the test were regarded as negative. In 1 instance typical histamine cephalgia was produced by this amount of histamine base.

When histamine base was given to 3 patients who had pheochromocytoma, the blood pressure rose approximately to 100 mm. more than the elevation obtained by the cold pressor test. This elevation of blood pressure was accompanied by the characteristic symptoms of a typical spontaneous attack.

Although the number of cases in this series is small, the intravenous injection of small quantities of histamine base may be considered tentatively as a worthwhile test in distinguishing the syndrome of pheochromocytoma from other clinical conditions.

PAUL MERRILL, M.D.

Duffield T. J., and Jacobson, P. H.: Cancer Mortality and Marital Status; an Analysis of Deaths Attributed to Cancer among the White Population of New York City during 1929-41. *J. Nat. Cancer Inst.* 945 6 03

During the years from 1939 to 1941 the recorded number of deaths from cancer in the white population of New York, New York (15 years of age or over) was 34,019. These deaths were distributed by sex as follows: single males, 3,393; single females, 2,255; other males, 15,011; other females, 14,459.

Using these figures and data in regard to the marital status of the population from the 1940 census the authors were able to draw the following conclusions from the study of various types of cancer:

1. In cancer of the breast the death rate among single women at ages over fifteen years was more than 1½ times that of other women. Between the ages of 15 and 34 years the rate among the married women was about one third higher than that among the single women, but at all ages over 34 years the single women had higher death rates. Between the ages of 45 and 54 the rate for unmarried women was 79 per cent higher than that for married women.

2. The mortality rate from cancer of the uterus was 25 per cent higher among married women than

among single women. Between the ages of 35 and 74 however the rates were apparently equal.

3. In cancer of other female genital organs the death rate was 41 per cent higher in single women than in other women.

4. For all ages over 15 years the death rate from cancer of the genitourinary organs in males was about equal in the married and unmarried groups. Between the ages of 45 and 54 the mortality rate among single men was 50 per cent higher than among married men, but it was found to be 25 per cent lower between the ages of 65 and 74.

5. At all ages over 15 years the mortality rate from cancer of the buccal cavity was 73 per cent higher in single men than in married men. The mortality rate was six times as great among men as opposed to women.

6. In cancer of the stomach the mortality rate was 20 per cent higher among married women than among spinsters. The difference among the males was not considered significant except after the age of 75 years when the rate for single men appeared to be lower.

7. In cancer of the peritoneum and other portions of the digestive tract there was no significant difference between married and unmarried women. The rate for married males was 11 per cent higher than that for bachelors.

8. There were no significant differences between married and unmarried groups in carcinoma of the respiratory system.

9. In all other types of cancer (analyzed as one group) in both males and females the rates were higher for single persons. ORLAND B. SCOTT, M.D.

Coller F. A., Job, V., Vaughan, H. H., Kelder, N. B., and Moyer G. A.: Translocation of Fluid Produced by the Intravenous Administration of Isotonic Salt Solutions in Man Postoperatively. *Ann. Surg.* 945, 13 663.

During the past decade, Coller and his collaborators have repeatedly directed attention to the potential toxicity of so-called "physiological saline solution," especially when large amounts are administered. They have emphasized that these dangers are increased manifold during the immediate post-operative period of the sick surgical patient.

Studies to determine the manner in which the human body handles large intravenous infusions of salt solutions were undertaken by the authors in patients undergoing combined abdominopelvic resection for carcinoma of the rectum. An explanation of the salt tolerance was sought in the excretions and retentions of sodium, chloride and water in the 30 hour period beginning with the operation. Solutions of various composition and tonicity were infused at regular intervals during this period.

The patients who served as subjects were selected only in that it was determined that they were free of gross cardiovascular and kidney disease.

The normal kidney is able to concentrate chloride taken orally at the rate of from 0.39 to 0.33 mEq per

milliliter. In spite of heavy salt loads no patient studied by the authors approximated this value. As a result of the increasing salt load and increasing hypertonicity of the extracellular compartment, osmotic relationships can be maintained only by a shift of water from the intracellular to the extracellular space. Loads of salt created by the isotonic solutions require a transfer of approximately 2 liters of intracellular water within 30 hours after operation. The edema, a symptom of postoperative salt intolerance may result not so much from the retention of water with salt as from the shifting of water from the intracellular to the extracellular space. It is unknown how much dehydration the cells can undergo before function breaks down and ceases. The brain cells are especially sensitive to change and the disorientation so often seen in cases of salt intolerance may be a symptom of this fluid shift.

The authors summarize their findings by stating that the injection of isotonic sodium chloride solutions was attended by an average retention of 53 per cent of the sodium, 46 per cent of the chloride and 19 per cent of the water 30 hours after the operation. Such retentions of salt indicate a withdrawal of approximately 2 liters of fluid from the intracellular compartment in order to maintain isotonicity. The infusion of hypotonic solutions resulted in the average retention of 27 per cent of the sodium, 32 per cent of the chloride and 39 per cent of the water during the same postoperative period. Extra water is thereby provided for excretory function of the skin and lungs and the intracellular compartment is not involved.

The human kidney under the conditions of the experiments, did not elect to guard a physiological saline solution.

The authors conclude from their experiments that if intravenous infusion is indicated in the postoperative care of the surgical patient, hypotonic solutions (0.45 per cent sodium chloride or better 0.38 per cent sodium chloride plus 0.11 per cent sodium bicarbonate) should replace the isotonic solutions commonly in use.

JOSEPH K. NARAT, M.D.

GENERAL BACTERIAL, PROTOZOAN AND PARASITIC INFECTIONS

Robenstein A. D., Tabershaw I. R. and Daniels, J.: Pseudo Gas Gangrene of the Hand. *J Am M Ass* 1945 129 659

Three cases of a new syndrome characterized by the rapid appearance of subcutaneous gas tumor masses within a few minutes after a superficial laceration of the hand occurred in 2 plants, where an alloy composed of 90 per cent magnesium was being used. Each patient had handled this material in a finely powdered form prior to the occurrence of the injury. It is possible therefore that an etiological relationship exists between the alloy and the syndrome.

Because this syndrome may simulate gas gangrene, it is important that its clinical characteristics

be borne in mind in order that unnecessary surgical procedures may be avoided. The syndrome is characterized by a rapidly developing swelling of a superficially injured part with crepitation and with an almost insignificant constitutional reaction.

SAMUEL KAHN, M.D.

Anderson D. G. and Jewell, M.: The Absorption, Excretion and Toxicity of Streptomycin in Man. *N Engl J M*, 1945 233 485

After oral administration, streptomycin is not absorbed in amounts sufficient to produce detectable concentrations of the drug in the serum. The failure of the drug to be absorbed from the gastrointestinal tract is not due to the inactivation of the streptomycin by the gastric juice.

After intramuscular or intravenous injection of a given amount of streptomycin, the curves of the serum concentration of the drug do not differ significantly except during the first few minutes after injection. Following the intramuscular or intravenous administration of a single dose of streptomycin, from 46 to 87 per cent of the dose injected can be recovered in the urine within 24 hours.

Streptomycin is excreted more slowly by the kidneys than is penicillin. It appears likely that effective blood levels of streptomycin can be maintained by administering the drug at intervals of from 6 to 8 hours.

The intrathecal administration of streptomycin in doses up to 20,000 units does not produce signs of meningeal irritation. With doses of from 10,000 to 20,000 units an appreciable concentration of the drug can be maintained in the cerebrospinal fluid for at least 24 hours.

No serious toxic reactions follow the injection of single doses of streptomycin in amounts up to 600,000 units or after the continued administration of the drug for periods of from 2 to 3 weeks, in doses totaling from 2,725,000 to 18,150,000 units. The intravenous and subcutaneous injections of concentrated solutions of the present preparations of streptomycin cause too much discomfort to warrant the use of these methods of administration. The drug can however be administered in an intravenous infusion without the production of unpleasant symptoms. Intramuscular injections are fairly well tolerated for periods of from one to two weeks. Therapy continued beyond this time may cause severe discomfort.

Three cases of infection due to a gram negative bacillus, and treated with streptomycin are reported. No conclusions concerning the efficacy of streptomycin can be drawn from them.

much as four million units per day. The streptomycin unit was that quantity of dry material which inhibited the growth of a strain of *Escherichia coli* in 1 c.c. of nutrient broth or agar.

In a patient receiving two million units of streptomycin daily, the blood was found to contain 31 units per cubic centimeter of the antibiotic. The intravenous administration of streptomycin was not attended by severe thrombosis of subcutaneous irritation when infiltrated. Intermittent intravenous administration resulted in a high concentration of streptomycin which then fell rapidly. Intermittent intramuscular injection appeared to be the method of choice because effective concentrations were present in the blood for from 3 to 6 hours. A high potency such as 100,000 units can be given readily in 1 c.c. of normal saline solution. Subcutaneous administration of streptomycin also maintained effective concentrations in the blood. Intrathecal single injections of 100,000 units were given for meningitis without any serious reactions and with significant concentrations of the antibiotic for as long as 24 hours. The nebulization of streptomycin for tracheobronchial pathology for a period of 4 weeks at 100,000 units per day caused no serious reactions. The oral administration of streptomycin at 125,000 units every 6 hours caused a significant reduction in *Escherichia coli* in the bacterial intestinal flora and was not followed by any absorption into the blood stream. Diffusion of streptomycin into the cerebrospinal fluid did not take place except when large doses were given parentally during meningitis. Placental transmission of streptomycin from the maternal blood stream to the fetus occurred readily after parenteral administration. Streptomycin was twice as concentrated in the biliary system as its average concentration in the blood. Liver function was not impaired by this antibiotic as evidenced by the normal values of bile and bile salts. From one half to three fourths of the streptomycin was excreted in the urine in 24 hours.

Toxic reactions to streptomycin were rare but may be manifested by chills and fever, generalized flushing, toxic erythema, urticaria, and joint pains. Streptomycin did not appear to have any effect on the hemolytic system. As a rule streptomycin did not impair renal function except when extremely large amounts were given, as a result of which there was evidence of temporary renal irritation.

BENJAMIN G. F. SHAROVITZ, M.D.

DUCTLESS GLANDS

Gabrielson, J. L., Kert, M. J., and Soffer, L. J. The Use of Thiouracil in the Treatment of Patients with Hyperthyroidism. *Ann Int Med* 1945 23: 537

Thiouracil was used in the treatment of 54 patients of whom 51 had hyperthyroidism and 3 had toxic goiter. Thirty-three of the patients were treated successfully with thiouracil for varying

periods of time, the longest period of continuous therapy being 10 months. Four of the patients had recurrent hyperthyroidism, and the remainder had diffuse hyperplasia or toxic nodular goiter.

Three patients with hyperthyroidism were successfully prepared for operation with thiouracil, but 4 patients with hyperthyroidism failed to respond satisfactorily to thiouracil. The latter were subsequently prepared with iodine and successfully operated on. In 11 instances thiouracil therapy was discontinued because of severe toxic reactions.

The following toxic reactions were encountered: conjunctivitis in 5 cases, edema in 1 case, drug fever in 4 cases, leucopenia in 1 case, and agranulocytosis in 6 cases. Some sort of toxic reaction was found in 31 per cent. The development of agranulocytosis or drug fever are indications for the cessation of therapy. Treatment may be safely continued in the presence of conjunctivitis.

Studies of liver and kidney function throughout the course of treatment failed to demonstrate any evidence of injury to these organs resulting from the thiouracil. However, instances of toxic hepatitis occurring during thiouracil therapy have been reported.

Because of the frequency and severity of the toxic reactions, thiouracil should be used under the following circumstances: (1) in the preparation of iodine-fast patients for operation; (2) in older individuals with hyperthyroidism, in whom operation is dangerous; and (3) in patients with recurrent hyperthyroidism who have been operated on twice or more.

SAMUEL KAND, M.D.

SURGICAL PATHOLOGY AND DIAGNOSIS

Stewart, F. W., Foote, F. W., and Becker, W. P. Mucoepidermoid Tumors of the Salivary Glands. *Ann Surg* 1945 122: 820

The authors for many years have been interested in a group of salivary gland tumors different structurally from the commonly recognized tumors of this type. They were unable to find adequate clinical and pathological descriptions of these tumors and were in doubt as to their terminology, histogenesis and prognosis. Gradually by correlating the histological structure and clinical course it was possible to distinguish two structural types, one capable of localized growth and the other of metastasizing. The term "mucoepidermoid" salivary gland tumor expresses two of the principle histological features. The authors believe these tumors represent a little more than 5 per cent of all combined major and minor salivary gland tumors and they deserve more prominence than they now possess.

As a group these tumors show a broad range of histological variation depending on the relative proportions of different cell elements which are present and tendencies to ward diffuse overgrowth by a single cell type. There is no gross uniformity; some are cystic, some solid, some encapsulated, others not. Recurrences may be structurally different

from the primary growth. It is likely that many of these tumors have been classified as cystadenomas, basalomas, cylindroma, adenocarcinomas or so-called mixed tumors.

The authors then list a number of cases in the literature which may be tumors of this classification. They believe that this group has been dealt with sparingly in the literature and is a group which is unfamiliar to many experienced pathologists.

The material for this analysis was obtained from the records of the Memorial Hospital, New York, New York, pertaining to approximately 700 major and minor salivary gland tumors of all types observed between 1925 and 1933. Of this series 45 cases were classified as mucocystic tumors. All of these contained mucous cells and cells with epidermoid qualities.

All evidence in this material points to the salivary gland ducts as the anatomic site of origin of mucocystic tumors. These tumors can be separated into two histological types—benign and malignant. The term benign as used here does not necessarily imply innocent behavior but does mean that thus far the authors have not observed metastases from these tumors. Malignant means a histological structure associated with the ability to force regional nodes and distant metastases.

In 14 of the 26 benign tumors the predominant cells were epidermoid in 9 they were mucous and in 5 they were basal. At least three cell types were represented in the majority and the presence of multiple cell types in large numbers was more characteristic of benign than of malignant tumors. In a restricted area, the pattern depends on the predominant cell type. If basal or intermediate cells predominate a uniform mosaic result with sheetlike groups of varying sizes, the peripheral margins of which are sharply delineated as seen in a basal cell epithelioma or a sweat gland adenoma.

In areas of mucous cells, one sees instead quite small or even greatly dilated ductlike structures which are lined by one or several cell layers. Some of these areas assume papillary qualities and not infrequently possess a central core of vascularized fibrous tissue. In some of the ductlike or cystic areas are found "mucus pools" which stain brilliant red with Mayer's mucicarmine. If there is overproduction of mucus, dilatation ensues with erosion of the lining epithelium, disruption of the basement membrane and leakage into the adjacent tissue. This may result in necrosis or a marked secondary inflammatory process with an associated foreign body reaction with multinucleated giant cells.

In foci of epidermoid cells, it is unusual to find complete dissociation from basal or intermediate cells, and when the cells assume squamous qualities there is apt to be a diffuse intercellular overgrowth. These cells are similar in size and shape, their staining qualities are uniform and mitoses are few. One is apt to regard the tumor as malignant until greater familiarity with its structure is obtained. About one third of the benign tumors showed certain

areas composed of cells hydropic and swollen cells similar to the clear cells of a renal adenocarcinoma. One may assume that these cells contain mucus but none takes the mucicarmine stain.

In 14 of the 19 malignant tumors, epidermoid cells were predominant and in only 5 were mucous cells even second most frequent. By epidermoid cells is meant cells similar to basal cell carcinoma and squamous cells without intercellular bridges and keratohyaline granules. Intermediate cells, slightly larger than a basal cell and with more vesicular nuclei and more abundant cytoplasm, were a frequent cellular component of these malignant tumors. Columnar cells were rare. True squamous cells with intercellular bridges and keratohyaline granules were found in 5 cases.

The outstanding characteristics of these malignant tumors is a diffuse proliferation of rather small, moderately hyperchromatic, rounded and oval cells in sheetlike arrangement with a tendency toward palisading at the outer layer surrounding the proliferating sheets and pegs of the tumor. The impression is one of a basal cell epithelioma with one thing added, and there is an appreciable resemblance to the transitional cell carcinomas of other locations.

Malignant tumors show little tendency to form microcysts. Tubular and papillary features are infrequent and mucus pools practically nonexistent. The histological structure of metastases sharply reflects the variable structure of the primary lesion. Mucous cells were found in metastases in 5 cases.

The 14 primary and 9 recurrent benign tumors varied in size from 4 mm. to 4 cm. in diameter, averaging between 2 and 3 cm. They were oval in shape and well circumscribed, usually with a poor capsule. Usually these tumors were moderately firm but not indurated. A majority were at least partly cystic and contained nearly clear opalescent or blood stained mucoid material, usually viscid. The nearly solid tumors were grayish white or grayish pink but not lobulated. About one-half of the tumors showed discoloration due to secondary hemorrhage and/or necrosis.

Of the 19 malignant tumors, only 10 were excised (4 primary and 6 recurrent). The majority were between 2 and 3 cm. in size and the largest 5 cm. Lack of encapsulation was a distinct feature and most of them were obviously infiltrative. There was much less cyst formation than in the benign tumors, and none showed grossly visible mucus aggregates. They were distinctly firm cellular, opaque grayish-pink, and homogeneous with fairly common hemorrhage and necrosis.

A study of the ages of the patients at the onset of their symptoms shows a general trend for the benign tumors to occur in a younger age group. Forty-two per cent of the benign tumors occurred in patients more than 40 years of age and 65 per cent of the malignant tumors occurred after this age. None of the benign tumors occurred after 60 years of age, but one fourth of the malignant tumors first gave symptoms after this age.

The parotid salivary glands were the most common sites of both benign and malignant mucoepithelioid tumors, the majority being benign. The other major salivary glands were involved only exceptionally. Nearly one third of the tumors (mostly malignant) occurred in the minor salivary glands in a variety of locations.

Painless swelling was the outstanding symptom in the benign series. Slow growth and absence of involvement of the facial nerve were commonly reported. Several patients had local pain or bloody sputum and 3 cases were found on routine physical examinations. There was a wide fluctuation in the duration of symptoms. Nine patients had symptoms for a year or more and several had had them for five years.

The syndrome was far more varied for the 19 malignant tumors. This was largely due to their location within the oral and nasal cavities and the more aggressive growth of these tumors. Eight patients (42%) reported a painless swelling as the original symptom. Three noted painful swelling. Others complained of nosebleed, a mass, lacrimation or a nasal discharge. One patient first noted a metastatic lump in his neck. Other symptoms which occurred during some phase of the disease were numbness of one side of the tongue, interference with speech, dryness of the mouth and sore throat. Lacrimation, trismus and facial nerve weakness were seen in 1 case. Pain was a prominent symptom in most cases sooner or later. Three of these cases gave a history of cachexia and weight loss. About one half of the patients reported a rapid increase in size of the mass.

Six of 10 patients had symptoms for less than one year. Two cases are presented as evidence of the transformation of benign into malignant tumors.

The benign tumors, whether recurrent or not, were nearly all described as firm. An occasional one was elastic or rubbery and only 2 were considered cystic. Most of the tumors were well defined but not as sharply as the so-called mixed tumors. Five of the 50 parotid tumors were firmly fixed and several others had infiltrated the skin. All of the primary tumors were single but 2 of the recurrent cases showed multiple discrete nodules. The 5 benign tumors of the minor salivary glands were submucosal except for 1 polypoid nasal tumor. Two of these tumors had ulcerated through the mucosa.

The malignant tumors, whether primary or recurrent, were firm, fixed, poorly circumscribed and infiltrative. Both submaxillary tumors fungated through the skin. One parotid tumor interfered with the facial nerve. All but 2 of the minor salivary gland tumors showed mucosal ulceration. The intraoral and intranasal tumors were complicated by erosion and penetration of adjacent bony structures.

In 11 of the 36 benign cases the tumors had recurred after surgery when first seen by the authors (5 of the 11 were twice recurrent). Late recurrence may be characteristic of these tumors. Ten of the recurrent tumors were parotid and 1 nasal.

Of the 19 malignant cases 9 were recurrent after surgery when first seen, (5 of the 9 patients had more than 1 re-excision). Rapid recurrence was much more likely in this group. Ten patients on initial examination showed clinical evidence of metastases to the cervical or supraclavicular lymph nodes. In 4 of the 10 cases the primary tumor was in the major salivary glands.

Distant metastases were seen in the cervical mediastinal para-aortic and iliac lymph nodes in the lungs, pleurae, myocardium and liver and in the subcutaneous regions of the face, scalp, axilla and abdomen.

In 14 of the cases of benign tumor treatment was started more than 5 years ago. Three have been lost to follow up and were free of disease 1, 2 and 2½ years respectively when lost. Nine patients were alive and free of disease, and 3 had recurrences which are probably inoperable. Two of the 5 year cures were from irradiation alone and 3 followed surgical excision alone. Four of the 9 cases were subjected to combined surgical excision and radiation treatment. Radon seeds were implanted in the operative area in each case. One case received additional external irradiation also.

The highly fatal character of the malignant group is shown by the fact that 7 patients are dead, surviving 2, 3, 5, 8 and 9 months and 2 and 10 years after treatment respectively. Five of these 7 patients had clinical or pathological evidence of metastases when treatment was begun. Twelve patients are living, 2 have locally uncontrolled tumors and 1 has subcutaneous metastases. One patient alone is alive and free of tumor after 5 years. Two are living 3½ and 2 years respectively and believed to be free of tumor. The follow up period in the remaining 8 still living is too short for significant comment.

The Effects of Crude and Purified Penicillin on Continuous Cultures of Normal and Malignant Cells. *Bull. Job. & H. J.* 11 19 1935 77 110

Continuous cultures of normal (rat) and tumor (human rabbit and rat) cells maintained in roller tubes as pure strains tolerate very high concentrations of penicillin sodium for very long periods of time.

It is possible to cultivate almost indefinitely strains of cells in plasma culture media with supernatant fluid containing penicillin sodium in concentrations of 5,000 Oxford units per cubic centimeter. Such successful cultivation apparently depends upon the character of the immediate cultural environment as well as upon the inherent tolerance of the cell strain.

No conclusive evidence of an increased tumor cell susceptibility to purified penicillin, when compared to that of normal cells, can be drawn from the results obtained on continuous cultures and on primary explants of tumors produced by the inoculation of continuous cultures of tumor cells into animals. The toxicity of crude penicillin filtrate is much greater than that of the therapeutic penicillin sodium and is perhaps due in large part to the toxicity of the mold medium from which the filtrate was made.

HOSPITALS; MEDICAL EDUCATION AND HISTORY

McGill, C. M.: Hernias and Serious Injuries. *J. Am. M. Ass.* 1945 139 673

The author demonstrates the value of preplacement physical examinations in industry by comparing data from five shipyards which conducted preplacement examinations with those from five yards which did not. The average employment of each group exceeded 100,000.

Accident frequency records showed no significant difference. The quarterly loss ratios or the ratio of incurred expense (including incurred indemnity and medical losses) to the total compensation insurance premiums was also studied. The mean loss ratio for the five yards conducting examinations was 37.13 as compared to 48.01 in the other five yards, which indicated costlier and more serious accidents in the latter.

It was not possible because of the variation in workmen's compensation laws to compare the two groups on the basis of total compensation expense. The average of serious cases and hernias per month per 1,000 employees, however, shows that the rate for hernias is over three times as high, and for serious injuries almost three times as high in the yard which did not conduct preplacement examinations as the corresponding ratio in the yard that did conduct such examinations.

'HITS STRIKES AND OUTS IN THE USE OF PEDICLE FLAPS FOR NASAL RESTORATION OR CORRECTION

VILRAY P. BLAIR, M.D. F.A.C.S. and LOUIS T. BYARS, M.D. F.A.C.S. St. Louis, Missouri

THE purpose of this paper¹ is to illustrate some of the underlying factors that can make either for success or for failure in the substitution of skin bearing flaps for lost or lacking nasal tissue. Such flaps may be used alone or supplemented with cartilage implants or free skin grafts. The need for nasal restorations or corrections might come from (1) congenital absence (total or partial) (2) postnatal growth irregularities (3) tissue loss through disease accident or surgical destruction.

PREOPERATIVE CONSIDERATIONS

The quality of final outcome and number of operative steps required may be more closely related to the thoroughness of preoperative study and planning than to the skill expended. In complex cases it is worth while to check repeatedly the tentative plan otherwise some oversight might necessitate a midstream modification causing delay increased operative steps and ultimate disappointment. Disappointment is not helped by the feeling that

more persistent preoperative study might have prevented the debacle.

This survey should compass not only the tissues of the external nose proper and the sources and kind of repair material available but also the condition of the foundation tissues (Figs 7 11 18 26) and of the nasal passages (Figs 5 8 9 15). The latter is unfortunately often missed. Fitness and fit are as essential here as in the foundation of a house. The proper time for securing these is before and not after the nose or the house is added. Therefore before considering the external nasal repair the underpinnings breathing space and the usable nasal remnants should receive careful scrutiny. Loss or displacement in the nasal framework or of the related cheek lip columella or septum should also be determined (Figs 5 and 16). When present correction of such loss or displacement should be at least visualized before the nasal repair is planned. Restoration of the foundation and repositioning of tissues to give breathing space are parts of one problem selection patterning and transplantation of repair material are parts of another problem. These two must at least be correlated mentally before surgery is undertaken.

Recorded sculptors of less skill than Phidias all preferred to materialize their ideas in clay before making a false cut on a marble block.

¹Presented before the American Association of Plastic and Reconstructive Surgery, October 7, 1945.
Bernard G. Sarnat, M.D., assisted in assembling the material for the case histories.

For camouflage and emphasis the greatly reduced prints in the figures have been appropriately blanked and pencilled but without intentional sacrifice of lines of verity.

²This study is based on selections from considerably more than a hundred flap restorations.

Fig. 2. Diagram of a forehead flap. Z, Z' for vestibular lining and columella. Lateral dashed lines (Z, Z') on the lower part show the minimum width of forehead flap for vestibular folding. Dark outline shows desirable width, often available in men with receding hairlines. Making dorsal covering and vestibular infoldings with adequate airway from forehead flap less than 5 centimeters wide can be difficult. 1. ala. 2. tip of nose. 3. glabella. P. pedicle.

b. Diagram and plan for infraorbital flap, whether arm or body applicable here. sufficient bone or cartilage remains to give form to the new nose (Fig. 18). Observation of graft lined flaps suggests that with no supporting framework a alar flap, patterned after the outer dashed line of b, the covering part, prevails and thinned and lined with contractile split skin graft should fall by itself into form when utilized as a fixed bed. Later the excess graft lining the vestibular part will be removed to accommodate the infoldings. Whether neck, trunk or arm, the pedicle comes from below. Note greater allowance for length of Z, Z'. The pedicle infoldings part of the flap should be between 2 and 3 cm across. (c b).

Diagram for a full model of the plan of the vestibular fold regardless of whether the pedicle is above or below. Z, Z' show the part of the infold used for vestibular lining. Z' the mesial element from which the columella was made.

RESULTS. A. GROWTH OF NOSE WITH SPLITTED FLAPS.

In this series of cases, teen age or younger, some useful comparisons can be made of growth changes in early repair. Disregarding the disparity of ages, an apt comparison can be made between the case in Figure 2 and that in Figure 3. Though the noses were small, the former, as repaired with a forehead flap and the latter with an arm flap.

The relation of size to growth of a nose made with a forehead flap will remain more stable and with an arm or sublabial flap will be rather stable if the major part of the supporting structures has persisted intact. Figure 4 presents a case in which the estimated allowance for growth proved insufficient.

In growing nose with vestibular lining and covering derived from foldings of the same flap, the similar growth impulse may in time cause critical wrinkling of the confined lining layer as can be seen by comparing Figure 5 with Figure 3 where repair was made from an arm flap. This was less evident of the forehead flap repair in Figure 2, as shown by the photographs taken 3 years after final operation in each case.

In Figure 5 repaired with forehead flap, done 1 1/2 months later age the disproportionate changes with growth are less evident. At no stage was there wrinkling of the vestibular lining. Figure 5 shows also that even in the use of forehead flap, it is necessary to make allowance for some shrinkage emphasized by the change in shape of the ala and tip in 3 weeks' time (compare g with h).

Regarding the cases in Figures 6, 7 and 8, sublabial infection, the common characteristics of development of the upper lip, the common characteristics of ulceration in the lip. In Figure 6, as made with infection of the nose or cartilage.

but allowance as made for growth and possible bony core-implantation. This accounts for the marked dorsal convexity of the completed nose. Figure 7 the child originally had almost no supporting framework, lacking even columella and premaxilla. Figure 8 the restoration of the nose closely bound up with that of the lower lip.

Fig. 3. A girl, 10 1/2 years old, with destruction following surface radium applied at 5 weeks of age. Condition shown in a and b. Primary application of a forehead flap. The foldings for ala and columella were shown and readjusted shortly afterward to give better breathing space. c and d. Photographs sent to us approximately 4 years after application and adjustment of the flaps. Comparing with Figure 2, it is shown that the right ala border has become lower than the left, but this could, even now, be readjusted. Seven operative steps, major or minor, were required over period of 3 years.

Fig. 3. A girl, 5 years old, had received destructive radiation in infancy and, in condition shown in a and b. Condition 4 months after surfacing the nose and restoring the vestibule with an upper arm flap c and d. Photographs taken approximately 4 years after final adjustments.

It is difficult at this time to determine whether all of the shortening shown in Figure 3 is real or partially due to some upthrusting in the pose of the photograph that was sent to us.

Five operative steps, major or minor, were done in less than 2 years.

Fig. 4. This supernumerary child was 8 years old when repair was initiated. Early arm flap repair failed to keep on third page following.

Fig. 2

Fig. 6.

Fig. 8.

pace with nasal growth. a, Shows radium destruction in infancy causing scarring and crumpled ala. c, After excision of damaged tissue, sufficiently extended to insure circulation in the transplant, an oversize flap was implanted in the belief that it would provide for future growth. d, Five years later the above allowance for growth had proved insufficient. At this time the original flap was removed and the distortion was released. An abdominal flap was jumped via the left hand and adjusted. b and e. Photographs taken 2 years after final repair. Twelve operative steps, major or minor, were done over a period of 8 years. The new nose is not central in its relation to the lip or the teeth.

Fig. 5. A girl 17 years old, was injured 9 years previously. a, e and f. Photographs show adjacent partial nose and cheek loss with incidental alar distortion and vestibular block. The skin graft on the upper lip had been applied shortly after injury. d and g. Taken 1 year after covering the right half of the dorsum with a forehead flap infolded to line the vestibule and piece out the ala. The intentional exaggeration of the alar circumference of the vestibule still shows. Gravity was expected eventually to correct the draw-up of the new alar border. b, e and h. Show final adjustment of cheek scar, alar attachment, and symmetrical shrinkage of the alar circumference but the alar border is still above the level of its fellow.

This required eight operative steps, major or minor, over a period of 1 year.

The alar draw up cited persisted.

Fig. 6. Congenital deformity in a girl 10 years old. a and b. Condition at first examination. After release of the uplift, repair was made with a right forehead flap, with a pedicle at the left brow, wide enough to supplement both lining and covering, shown in c. d, The covering part of the flap is in position with a prolongation between the separated ala to piece out the lip. e and f. Last observed result, 3½ years later. This was done in six operative steps, completed in 3 months.

Subsequent growth will likely modify the convexity of the dorsal line.

Fig. 7. Congenital deformity in a girl, aged 12 years. a and c. Show the condition with the lip repaired and a cartilage previously inserted in the upper two-thirds of the dorsum. b, d and e, A flap from the right lower abdominal quadrant was jumped via left wrist to the dorsum after

removal of the nasal covering and the lower part of the original cartilage implant. Later the columella came from an inner lateral palm flap implanted first into the nasal tip and subsequently into the lip. b and e. Owing to circumstantial delays, the 8 major and minor operative steps were spread over a period of 4 years.

Fig. 8. A girl aged 17 years, with history of premature birth reported weight 1½ pounds. Congenital infection with early ulceration of lips and nasal lining. Left vestibule almost obliterated, columella retracted and much of lower lip missing. a and b. b, The two vertical lines between s and t indicate full thickness incisions which, after discarding the scarred lining and the related cartilaginous septum, permitted the turning in of the skin to furnish attachment to the future lining flaps. s' t' s in c. X and W indicate full thickness flaps (8, b). In c, flaps X' and W' have been rotated to give vertical length to the lip. F and Z indicate primary raising of the nasal flaps. d, The nasal flaps F and Z were again raised, the distal two-thirds of each thinned doubled back and fixed with sutures to heal, raw to raw to help piece out the vestibular lining.

The nose as shown in e and f was accomplished by turning in s' t' s as partial lining, attaching the nasal flaps F and Z sutured in the midline. The columella came from some extra width on the mesial border of Z, originally provided for that purpose. We have several times used this double flap where the forehead was wide but too low to furnish it in one piece (Fig. 3a). The dorsal line of junction can, with careful cutting and suturing, be made all but invisible. Where a nose is patched with an arm flap, the line is apt to be evident, less so if enough material was provided to allow a secondary adjustment.

e and f. Show the final result. At recent steps a crescent piece was sawed from the mandible to shorten the vertical chin-lip length. Later the two halves of the lip were separated. A folded arm flap was implanted into the midpart to give more than double the transverse width of the previously tight lower lip. At the time of transfer the rolled edge was left overfull to permit later an attempted reproduction of the natural slight ridge of the mucocutaneous junction.

This was accomplished in 8 major or minor steps done in 5½ years time.

A wider insert would have avoided the slight "V" at the right border.

SERIES B DEFORMITIES INCIDENTAL TO A SHORT NASAL TUBE

These deformities might be congenital, as in Figure 9, or due to infection, as in Figure 10, or acquired in growth, as in Figure 11. In some, correction might necessitate synchronous lengthening of the nasal covering (Fig. 11).

Fig. 9. a, Girl, aged 1 year, with columella and vestibular floor short, but with full vertical length of the dorsum. Correction required several very distinct steps. The first was accomplished by dividing the short columella from the lip and septum. This stubbin of columella was fixed in an advanced position, shown in b. In b, -a roughly indicates

lining incision that traversed the floor of the vestibule and extended well forward in each lateral wall. b-b indicates the lower border of the ala, d the original position of the columella. c, Wide undermining permitted the border and lower part of the alar covering to be moved downward and forward, with the resulting lateral defect in the lining, indicated by a'-a-a' while the liberated stump of columella was moved forward to d'.

d, The lining defect was filled in with the two halves of a swallow tailed lateral palmar flap, introduced through the nostrils. After circulation was established, the pedicles, ff were divided in the midline of the floor. The columella was later placed out from the remaining palmar pedicle. e, indicates the bare lower border of the septum.

c Show the result of these implantations but which have not as yet brought the nose or lip sufficiently forward. To correct this, the cw columellar patch was freed from the septum, the lips and cheeks were freed from their intranasal attachments by incising in the depth of the upper sulcus, and with the columella were sutured in further advanced position, the circulation in the columellar patch being maintained by its anterior and posterior attachments. f and g Show the final advancements and the columellar patch.

This was done in seven operative steps, which for extrinsic reasons were extended over 2 years.

Fig. 10. A woman, 38 years old, had a flat bridge since childhood with history of ulcerations and repeated treat-

Fig. 1

ments. a and c, Show saddle nose and loss of vestibular lining, but dorsal covering and columella of sufficient length short nasal tube. Disregarding the presence of the columella which was lacking in Figure c, the plan of lengthening of the vestibular floor and walls is identical with the exception that in Figure c, d, the swallow tailed flap was introduced through the common nostril space while in this case it was introduced sublabially.

b, Shows the immediate result of the tubal lengthening which for lack of cartilage support was but partially maintained in the healing process (see c) but a secondary undermining of the dorsum and the implantation of cartilage gave the result shown in d and f. The above procedures give about the limit of lengthening solely by additions to the lining. This was accomplished in 7 operative steps, major or minor, over a period of 15 months.

Fig. 11. Fairly postnatal development with shortening of both the dorsal line and the nasal tube in a man, 21 years old. a and d, Here the approach was through an external incision as indicated by the dashed line in a. The

superficial tissues were stripped as far down as the dotted line, at which level the alar cartilages and floor of the vestibule were cut across. The lower part of the septum and the related soft tissues were mobilized as in Figure 10. In Figure c the lining flaps were entered from below met at the dorsum and were wedge shaped. In this case, the lining flaps entered through the dorsum and met at the midline of the floor were cut across at the dorsum square-ended both above and below. The covering flap in b, came from farther up on the pedicle. Later developing scar constrictions were dealt with through the nostrils the need for the latter is less frequent after implantation of a forehead than of an arm flap. b, Shows the condition several months later c and e. Views of the final result, show the dorsal line brought forward, accomplished by surface readjustment and dorsal implantation of costal cartilage. Four years later always were reported satisfactory. A total of 7 operative steps was done in 1 year's time.

Split graft in forehead could be replaced with pigment injected full thickness graft.

FLAPS

There are three general sources from which the flap might be taken directly or jumped (1) the hair free regions of the forehead and face (2) the arm hand anterolateral areas of the trunk and the groin (3) pedicle flaps derived from the nose (Figs 1 27 and 29) Of prime importance in the selection of tissue for a flap is the recognition of variations in the suitability intrinsic to the donor area. The outstanding characteristic of those taken from above the mandible is quality from below the clavicle is quantity. In hair free areas of the neck those factors merge but with quality still dominant (Fig 17) A more detailed but terse differentiation of aptitude is given in Table I

Human flap material is precious. The surgeon will best serve the patient and himself by first making patterns from plaster-clay restorations of what he is attempting to re-establish (5 a). One that does not exaggerate the surgical possibilities serves as a usable working pattern helps the patient to visualize better the aimed at result, and gives some idea of the intricacies involved. Even then it is hard to gauge the patient's buoyed up expectations. It is good practice to hazard the remark that the operative result will most likely fall quite a bit short of the model—unfortunately often true. In faces both operated upon and not the natural color and mobile expression will camouflage moderate defects in contour which on the white cast stand out glaringly (9)

Fig. 13.

Fig. 13.

Fig. 14.

REPAIR OF DESTRUCTION IN THE TIP AREA OF THE NOSE

Incisions of this type establishment of breathing space is usually an essential step. The main flap can be taken from the arm, forehead or neck or jumped, like the lining may be supplemented by a flap from the dorsum. Cartilage implantation may be necessary.

Fig. 12. Traumatic loss of tip of nose, 1 month previous. In 1 man 8 years old. a, Flap outlined laterally and undermined but the distal end was not detached. On account of poor circulation, 1 more operative step was required before it was considered safe for transfer. A piece of adhesive covers the missing tip. b, Three more operative steps are necessary. c, It required one. d, Hung, two adjustments and a postauricular skin graft on account of a poor circulation which threatened loss after each operation. This difficulty of establishing circulation is extraordinary for face flap. e, The case. f, Figure 14, the age of the older man may have been factor in permitting the raising and implanting and replacing of the pedicle of the flap at 1 step.

Fig. 13. Not even the age of 3 months and 1½ years, patient had ulcerations of undetermined cause. a, Shows condition at our first examination of the girl, 8 years old. b, Forehead flap was put down in place. This as followed by the usual adjustments. c, Patient returned 10 years later. But no operation was done to bring forward the tip of the nose and split skin graft covers the original lip scars. This required four operative steps in all.

Fig. 14. a and c. Loss of tip of nose from cancer past. In 1 man 32 years old. A triangular flap as raised from the left cheek with the base at the bridge of the nose and was transplanted immediately into the defect. d, It was cut and adjusted pedicle on nose and in back, using skin graft to fill out latter. b and e. Taken 20 months later. This man had a known cryomovable skin with almost no underlying fat which three factors seemed to arrest the necrosis attempt to complete the operation in two operative steps. Compare this with case 1, Figure 2.

There is room for judgment in each case but the success here hardly warrants repetition of the two-step operation.

Fig. 15

Fig. 15 a and c, One year after loss of tip and columella narrowing of the vestibular floor and inspiratory collapse with airways obstructed in a man, 40 years old. The repair was made in the standard way from a forehead flap but it lacked intrastitital support. b, The inhalation collapse was controlled by undermining through incisions just within each vestibule, permitting insertion of thin strips of costal cartilage with perichondrium, facing medially to cause a

slight outward bulge. Through incision made at each labial alar junction and undermining, a narrow stiff strip of cartilage was inserted which restored the width of the vestibular floor d and e.

The result was attained in six major and minor steps in 6 months. We have through the same approach put in a single piece of booped cartilage, or a single piece for each side can be inserted through a short dorsal skin incision

Supraclavicular flaps To have the completely made nose of acceptably small size especially upon a woman the part of the flap that will form the alae and tip and be infolded for lining must be made very thin and at least 5 centimeters wide (Figs 16 and 26). This is often not possible on a woman's forehead unless some scalp be included or taken as a bilateral double flap as in Figures 8 and 32. In older men however a receded hairline may become a blessing (Fig. 15) (5 a 8 a).

Face forehead and small neck flaps can ordinarily be safely transferred after two preliminary steps (Fig. 12 was an exception) (1) Make circumferential or both lateral incisions leaving but a small artery-carrying distal pedicle undermine completely but avoid stripping the periosteum (2) After 10 days or longer but only after determining total absence of edema and the efficiency of the proximal blood supply by finger pressure on the distal pedicle divide the latter and suture (Fig. 13).

With a well prepared forehead flap it might be possible and expeditious to thin infold and completely attach the whole nose at one sit

ting. However caution may dictate final thinning of the dorsal part only and temporary adjustment of the infolded part at the time the flap is first brought down. To insure a free vestibular airway without grossly increasing contour secondary drastic thinning of the infolded part will ordinarily be required. The one step thinning and affixing operation is most suitable in making a large nose of an older man where the blood supply is usually generous. For small noses the two-step application is almost mandatory.

A forehead flap with a temporal pedicle is poorly adapted to make a complete nose but can be used for dorsal covering lining (Fig. 6) or patching the cheek (Fig. 23).

Infraclavicular flaps Arm or body flaps should be raised in at least three stages spaced at proper intervals. (1) Make but one lateral incision at a time preferably full length down to the muscular fascia and undermine in that plane more than one half way across the proposed width (2) 10 days to 3 weeks later make the second lateral incision and complete the undermining (3) after a similar interval or longer cut half way or completely across

Fig. 16

Fig. 17

Fig. 18

Fig. 6. A man, aged 33 years, had been injured in a plane crash. Following this, he had unreduced nasal fracture. Cartilage and ivory implant had been introduced some weeks later. Nose was crumpled, columella retracted and alarway obstructed. a and d, Condition at our first examination. b, Used local anesthesia, the lower lateral cartilages, related mucous lining and vestibular floor scars were removed. The base of the columella was released and flaps of alar skin were implanted in the floor defect, thus advancing and lowering the upper part of the lip and the stub of columella. The lower border of the nasal covering was turned in and sutured; the lining established blood supply for a turn-down lining flap. and e The lip was shortened at its base to expose 4 millimeters of upper teeth. The dorsal covering and the vestibular foldings came from the forehead flap. Five major or minor steps were done in 8 months' time.

Fig. 17. Healed burn from gasol explosion a year previously in man, aged 37 years. Condition at our first examination is shown in a. An outlined upper neck submental, left submaxillary flap, with base at right facial

artery for nasal repair is partially shown by the submental lines in b. Completion of the work. The donor area of the neck was grafted. Incidentally the scarred lower eyelid was released. This and the cheek were grafted. The covering of the right upper eyelid was made from two scarred forehead flaps, the conjunctiva having been sufficiently released. It required 9 operative steps spread over a period of 2 years to restore eyelids and nose.

Fig. 18. a Condition after excision of upper lip, right cheek and nose for greatly distorting lymphangioma, in a woman 24 years old. The soft tissue covering of the nasal bones was turned down to line and stiffen the central part of the nose. The nose was made from the arm with second and third foldings, but after this had healed in place the upper lip and the lower part of the nose were still retracted. To correct this a thicker piece of cartilage than that indicated in Figure 5, but with the same technique, was inserted with the result shown in b and c. At the same time the lip was shortened. b and c Front and side views, respectively, 7 years after repair was begun. This was done in 17 operative steps over a period of 8 years.

DIFFERENTIAL CHARACTERISTICS OF SUPRACLAVICULAR AND INFRACLAVICULAR FLAPS

TABLE 1 —

Flaps taken from face or neck	Flaps taken from trunk or limbs
<i>Inapt</i>	<i>AM</i>
1 Hair free donor areas may be embarrassingly limited especially on the forehead of a woman or the neck of a man	1 Can be made almost any size A. Body hair may be entirely negligible
2 The scar of the donor area is always in sight, though this can be more or less camouflaged by skin graft and intradermal injection of color. Try to avoid a forehead defect on a woman.	2 Most donor sites are hidden by the clothing
	3 Certain of the objectionable factors cited below in the <i>inapt</i> group do not hold true for flaps taken from the front of the wrist or border of the palm. Both are hairless and the latter is of good consistency and color and does not shrink. These latter can be particularly appropriate for certain small repairs such as restoration of a columella or an ala.
<i>AM</i>	<i>Inapt</i>
The forehead flap is intrinsically the more desirable. It is relatively firm in substance with just sufficient elasticity to retain some spring making it self-supporting. When loaded to a sharply molded form it will shrink very little in healing or subsequently.	1 The tissues are relatively flabby and, with the exception noted above unless supported are apt to shrink to an embarrassing extent
2 The constituent layers are rather uniform in thickness and consistency which facilitates symmetry of molding.	2 Such flaps lack definite cleavage planes and closely adjacent areas may vary greatly in skin thickness and in the quality of the underlying tissue all of which tend to negate both symmetry and sharpness of molding.
3 Total blood supply is relatively greater and more easily trained to a narrow pedicle with ordinary precaution. Hesitancy of healing or slough is rare but can happen.	3 The total blood supply will average less, its sources are more diffuse, a greater number of operative steps may be required to establish an efficient pedicle, or even one of doubtful value.
4 The basic blush color will persist or be early restored.	4 In flaps taken from below the clavicle the basic red is deficient or absent however this can be at least partially compensated by suitable injection of color intradermally but will yield no variation in blush.
5 Flaps taken from other nonhair-bearing parts of the face will be about the same qualities but of necessity will be much smaller.	5 The body hair may be negligible or so profuse as to require surgical depilation control with chemical depilatory agents or razor.

the distal pedicle and if circulation warrants the nasal covering part of the flap might be thinned and put up at this time. Never cut across the distal end until the flap has acquired an adequate circulation as proved by pressure test. Venous engorgement can cause gangrene in a pendant flap in spite of a generous blood supply.

At some step the pedicle of a long arm or body flap might be partly or wholly tubed or the raw surface of both pedicle and bed can be covered with split skin grafts at this time except the area to which the excess of pedicle will ultimately be returned. It is desirable in the original planning of a flap to allow for proximal lengthening should a partial loss occur at the distal end (Figs. 30 and 31).

For disproportionately long and narrow flaps on the trunk or neck sectional tubing interrupted by temporarily retained attachments to insure immediate blood supply is a practical plan. These supply bases are later detached and tubed consecutively.

With a forehead flap where the pedicle comes from above a few tacking sutures are sufficient to hold the transplant in place but to compensate for the pedicle drag of a flap brought up from below we use one row of hurried very fine white silk sutures on either side so placed as to give some up-crowding when tied with a superficial row of fine sutures to insure accuracy of skin approximation. With a forehead flap the hurried sutures might be omitted. In either case the superficial sutures are of black silk the knots are not drawn sufficiently tight to leave marks and might be removed in 3 days. These are replaced by a one-layer patch of gauze affixed with flexible collodion. A heavy skin suture deeply placed at the lower end of the alar bulge may be used both to fix and shorten the vertical base of the bulge which will tend ultimately to give a more natural lateral fullness to the ala.

The weight strain is further eased by a gauze strip fixed to the skin with fresh flexible collodion lengthwise to the pedicle below and above to the forehead. If into this traction line a section of elastic rubber band is introduced the lift will be more uniform.

Fig. 20

SERIES D. RESTORATION OF UPPER PART OF NOSE

The cases selected for this and the following series give even greater emphasis to the necessity for exact determination of the real extent of loss or distortion and the mode and possibilities of repair before correction is instituted. Distortion of usable tissue should be entirely released before the flaps are put in place yet the preparation of delayed flaps must usually precede the opening of the bed in which these rest. We have found tape measure, plaster cast of this condition, corrected with modeling clay to be at least a partial solution to the what and the how of this dilemma (see Figs. 9 and 20 and ref. 5-b).

Forehead flaps should be cut very exact. With unrestrained subcuticular flaps, an allowance should be made for shrinkage. An incidental correction as in the case of Figure 3, shows that it may be difficult to estimate how much addition to any eyelid or its foundation will be really needed. Here an overcorrection can be dealt with by simple excision, while secondary additions are apt to be as complicated as the original implantation (Fig. 3).

Fig. 19. Saddlenose: loss of vestibular lining and columella in woman aged 28 years. a, Condition on first examination with scarred lining and a threadlike columella. b, Immediate result of wrist flap implantation used first to vestibular lining after undermining up to the glabella and pulling down the nose. At second step, the pedicle of the wrist flap was used to make the columella. c, Commercial poster exaggeration of type shown in b, which is an acceptable one for certain faces. d, The patient was satisfied and who should have been, but thought further improvements could come by inserting strip of cartilage into the dorsum. This proved to be a minor operation but a major blunder (compare b with d). e, The result obtained after eight subsequent steps, including some actual lengthening of the dorsum. Fourteen operative steps, major or minor, were required over a period of almost 5 years.

The first blunder was not resting in what was satisfactory to the patient. The second was that bringing forward the bridge of that tilted nose upset facial balance. The third was the compromise attempt to steal narrow covering

Fig. 2

Fig. 3.

and lining flaps from just above the brows in the hope of avoiding a grafted forehead. The flaps obtained were too narrow to give proper length to the dorsum and undermining of the forehead tissues to above the hairline failed to prevent drawing up of the brows. This latter gives an apparent overlengthening to the dorsum of a still turned up nose: a grievous error.

Fig. 30. a, Saddlenose, the result of an unreduced fracture 12 months previously in a woman 20 years old. b, Attempted correction by intranasal chisel-mobilization and wire fixation at first gave promise of being acceptable but with subsidence of the postoperative swelling, the lack of bony fixation, due to too early removal of wire, permitted a progressive distortion, as shown when she returned 6 months later. Adequate fixation for a sufficient period should give union where there is any bony contact. The plan we have used is an interstitial wire loop embracing the nasal spine above and fixed to the maxillary incisions below. This can be retained for 3 months if necessary. c and d, As a secondary attempt, the vestibular portion was completely severed from the bridge by transverse incision, see d. Subsequently the natural dorsal covering was turned in to line

the defect and the whole was covered with a previously prepared forehead flap that had a temporal pedicle shown in d. e, As with our first attempt, the immediate result appeared to be quite satisfactory, but 7 months later the lower part had slipped backward, as seen in a similar case Figure 11. b, f, Final result was further helped by implantation of costal cartilage into both the dorsum and columella. A total of 3 operations with 3 failures due largely to lack of sustained postoperative fixation of the mobilized mass, was required over a period of 2 years.

Fig. 31. a and e, Healed result of extensive cauterization done 3½ years previously on a woman aged 39 years. The dashed marks on e indicate the source of the lining flaps. c, The flap tissues surrounding the defect outlined as in e were undermined, turned in to give a ridged lining to the previously depressed dorsum. The surrounding tissues were further undermined to widen the bed for the covering flap. d, The forehead flap was put in place with the dorsal ridge maintained by temporary mattress suture. b and f, Result shown 6 months after completion of the correction (8, c). In this case 3 operative steps were completed in 7 months time.

Fig. 2.

Small patches of adhesive plaster prevent the cutting in of this necessarily tight mattress suture. Gauze was used for this purpose might cause necrosis.

Fig. 2. A man, 9 years old subglabellar fracture displacement from airplane crash. There were impingement on the nasolacrimal groove, great displacement of the left inner canthus and separation of the lacrimal sac on this side. a, and c. Condition at our first examination 6 months after injury. e. Result obtained by removing displaced bone and supporting sac repositioning of canthus fixed by transnasal 40 day gut suture. Overcorrection will subside after gut absorption. d, The superimposed diagrams indicate the repair flap and also the position of use. The displacement of the right inner canthus as partially corrected at this time by buried suture. b and e, Final result. This required but operative steps with 3 years intervening.

The right inner canthus could have been brought farther medially. The forehead defect was overcome mostly by wide undermining and suture. The remaining uptilt of the inner end of the right brow could be further corrected by a "Z" flap operation, but the patient wished to avoid this additional step. We have seen several such injuries due to rifle wounds in soldiers. If both eyes were intact, the man was grateful for the correction, but where one eye had been destroyed, he was apt to complain of the resulting narrowed visual range of the remaining eye.

Fig. 3. Ulcerations of face, mouth and pharynx, starting 20 years previously in a woman aged 43 years. a and c,

Saddle nose perforation of inner canthus, and loss from the upper part of the cheek, causing a distortion of the lid, extending to the outer canthus. d, A too narrow and too short forehead flap with right temporal pedicle as cut. The distal end was split. The cheek scar had been opened as far as indicated in d, which was not far enough. Nasal lining was obtained from the lower part of this flap. The insufficient upper part but partially filled the defect. Later the pedicle was cut across and returned to the forehead while the medial portion filled in the defect resulting from the letting down of the nose. At this time the remaining raw area was grafted. The tarsus is still not in full contact with the globe. b and e, Final adjustments of the flap. The transverse ridge on the nasal part of the flap, 1 week after final adjustment, is partly swelling and partly an allowance for spontaneous drooping of the nasal tip. b is c, the residual retroption, still so evident in d, has been partially corrected by liberation and insertion of a full thickness graft from behind the ear. This required 7 operative steps, major or minor completed in period of 5 months.

The primary fault here was making the forehead flap too short and too narrow. A longer flap could have permitted opening of the full length of the cheek scar shown in c, and greater width would have brought the tarsal border up to its proper position, thus avoiding the several subsequent steps. Further the supplementary skin graft is also too small, one wider and longer could have compensated for much of both faults.

The use of the inframandibular or infraclavicular flap gives no choice but for at least a two-step operation for affixing the flap attachment and final molding. Only the dorsal attachment with corresponding thinning can be done at the time of transfer. The special thinning for the columella and alar infolding is of necessity postponed until after establishment of the new blood supply and the division of the pedicle (Fig. 31). The vestibule is lined and the columella formed by infolding

of the extra length of the nasal flap already provided for this purpose (Figs. 1 c and 16). In a nose intact above the vestibule any needed lining can usually be derived from the original dorsal covering but in a total restoration an extra flap may be needed (8,a). It may be desirable but more frequently not practical, to make the columellar infolding wide enough from above down to admit later a cartilage transplant to support the rounded tip so common to total noses thus made (Figs. 20, f, 26).

Fig. 24.

Fig. 25.

Fig. 26.

SERIES V. SUBTOTAL RESTORATION OF THE NOSE

Usually a sufficient amount of the nasal framework remains. In certain cases, restoration of the dorsal line can be more easily attained by bone cutting than by cartilage implantation, but both might be used in a given case (Fig. 26).

In all restorations, whether great or small, integrity of the lining is as important as the covering. Restorations after total loss are done on the same lines but an extra nasal flap or graft may be required for lining of floor, dorsum, or both (3c and 8a).

Fig. 24. a, Subtotal destruction of the nose by cancer paste, in a woman 35 years old. b, Result 12 days after repair with forehead flap for covering. The lining came from turning in the remaining dorsal tissue. Repair completed in four operative steps over a period of 3 months.

Here a forehead flap gave a good dorsal line without other support.

Fig. 25. Auto accident caused subtotal loss of bone cartilage and covering in this 17 year old girl. a, A lesser loss than in Figure 24. Note the now too prominent re-

maining part of the bony bridge. b, Result of chiseling off the hump and approximating the bones before transfer of the repair flap. c, Repair with an arm flap. This gives a rounded tip, characteristic of a repair with almost any subclavicular flap (Fig. 17) as distinguished from a forehead flap repair (Figs. 24 and 26). This required 8 operative steps, major or minor, in 6 months.

Fig. 26. Healed subtotal cautery destruction of the external nose: left antral wall, cheek and lower eyelid in a woman, 69 years old. a and b, Repair made with flaps, a, b and c. At intervals, the left forehead flap was sutured into the freshened cheek defect with the mesial edge being turned in also to supplement the nasal lining of that side. At the primary raising of flap c, the lateral incision was made to the bone for right cheek fixation. c In molding the nose, flap c was rotated to pierce out the lining of the left side, b furnished dorsal covering and vestibular infoldings. With the settling of this soft tissue nose there was sinking of the lower part of the dorsal line. In the case in

(Continued on following page)

Fig. 30.

Fig. 31.

SERIES C. ARM FLAPS

Given a sufficiently bare area, a forehead flap may be cut to the desired size with little or no allowance for shrinkage (Fig 1 a) but for the arm or body flap (Fig 1 b) there is not only a natural tendency to shrink, for which some allowance should be made but the weight of the pendant pedicle tends to elongate the latter at the expense of width so that what at first appeared to be ample may have to be supplemented or the whole transplant discarded. It is for this reason that we cut an arm flap not only wider than apparently needed but make the pedicle even wider than the lateral extensions for the alae (Fig 7 h). The extra weight also demands more meticulous suture or an overlay of the borders of the flap to be adjusted later. Supplementary elastic support of the looped pedicle by rubber band traction, anchored to collodion-affixed gauze patches, will greatly alleviate weight strain at the suture line.

For comparison of adaptability see Table I and Figures 30 and 31.

Fig. 30. Sloughing arm flaps. Reactions still four-plus after four previous courses of treatment. Nose operation was uneventful after usable flap was secured. (See discussion of case in Figure 10)

a, A diffuse slough in an inner arm flap after making both lateral incisions and complete undermining in one step. The flap was abandoned on account of diffuseness of the slough. In several of our earlier cases, with success attributed to "fool's and beginner's luck," we raised large arm

flaps but a proper delay will likely eliminate the difficulty.¹ No flap should be transplanted the circulation of which had hesitated sufficiently to cause blebs, deep discoloration or diffuse gangrene. Such a flap would most likely not survive both thinning and transfer (Fig 30 a). We would consider worth while the attempt to use a flap that had suffered a sharply outlined distal loss from a frank gangrene provided the flap was still sufficiently

¹ A moderate activity of chronic acne that frequently follows a train trip or other accidental irregularity can usually be quieted and the patient made operable by one exposure to radiation. Proper length and intensity

flaps in two steps, but a good routine is a minimum of three steps.

b, Sharply outlined slough of a flap from the outer surface of the same arm after incising and raising the flap in two steps, but still without dividing the lower pedicle. Because the slough was sharply outlined and limited to a distal fourth, the flap was muzzled along until it had completely healed without any suggestion of change or impaired circulation. c, Spontaneous drawing in and healing of the damaged area, when the flap was successfully used with no hesitation of the circulation. Subsequent observations have forced the conclusion that in this and other losses, the fault was with the plan and not the tissues. This is also emphasized in the case of Figure 31 in which there was no blood dyscrasia.

Fig. 31. Partial raising at two sittings. At the time of application, circulation in the flap appeared adequate but it sloughed following implantation see a, b, Flap was taken down and allowed to heal with good circulation throughout the remnant. Fifteen months later with some secondary lengthening at the base, this flap was again put up, b, with no hesitation. The skin graft repair of the arm, shown in b, was done while awaiting recovery of the sloughed flap. In c, the transverse division of the healed in-place flap was at the level of the mouth slit. Higher than that is not safe as shown by the shortening which occurred after releasing the weight of the pedicle. (For discussion of case see Fig 18)

long or could be lengthened (Fig 30 b). After a second hesitation the flap should not be used. Forced abandonment of a flap at any stage is an embarrassment to the surgeon and more so to the patient. However loss of a transplanted flap is a catastrophe (Fig 31).

Correction of deformities resulting from trauma or disease. The first move in the repair of the donor area is the return and adjustment of the unused pedicle. After this has been transferred and the desired surgical correction made the remaining deficiency at the donor

Fig. 32.

Fig. 32. This case emphasizes the need of continual postoperative caution in any congenital or acquired infection.

Nasal and throat ulcerations for 2 years previous to recognition of the cause. Recent treatment of this 20 year old man had brought his blood reaction down from four to two-plus. At our examination he had scarring of the pharynx and palate. Internal nasal destruction and some full thickness loss. Medication was discontinued for a

period before operative correction was undertaken, as is our custom. We used two forehead flaps, one for lining and one for covering (Fig. 8). After these had healed in place, he was sent home for rest and further intensive treatment. Later we inserted cartilage graft into the dorsum, with the result shown in b and c. The length of time treatment was continued after cartilage insertion is uncertain, but he returned 7 years later with the wreckage which is shown in d and e.

site should be eliminated. Granulating or rough scar must be camouflaged or hidden. The borders of small defects might be undermined and approximated, while others must be grafted. It is hardly practical to use a full thickness graft at the time of flap transfer. A split graft might be less conspicuous if drawn tight over a 3 or 4 week old bed of smoothly trimmed granulations as is our common practice on the forehead. On the trunk, residual disfigurements can be hidden by clothing which is also true of a man's arm. In a woman an arm flap should be taken preferably from the inner surface; she can quickly acquire the habit of holding the damaged area close to the chest which makes a smoothly grafted area quite unnoticeable.

It is the exposed donor area of the forehead or arm and repair tissue that does not blend with the surrounding color that chiefly attracts attention. It is very seldom that an infraclavicular graft or flap will have any of the natural facial blush after transfer but it may become more tanned than natural. No matter how perfect the technique, a marked color discrepancy will vitiate an otherwise

quite acceptable result. Most women but few men will use cosmetics or surface stains. The natural red comes from the depths of the skin and surface applications are but easily detected substitutes that lack the true blush coloring. To match free skin grafts and pedicle flaps more nearly with the surrounding skin, pigments can be instilled into the derma of transplanted skin with fine needle points (9).

On the forehead, the original split graft is later discarded for an evenly fitted full thickness graft which is allowed to season before intradermal color is injected. The natural changing face-tinges are live and these cannot be duplicated even by color instillation, but this method is still our best substitute. The tenacity with which the transplant clings to the color characteristics of its source suggests the possibility of some intrinsic local control. For example, grafts and detached transplants taken from below the clavicle will in most instances, eventually lose all vestige of red, while flaps from cheeks or forehead, also postaural grafts, will retain or regain their natural blush shade.

OBSERVATIONS ON THE TREATMENT OF ADENOCARCINOMA OF THE UTERUS

LAMAN A. GRAY, M.D. Major M.C. A.U.S. Louisville, Kentucky MILTON FRIEDMAN, M.D.,
Major M.C. A.U.S. New York, New York, and WILLIAM S. RANDALL, M.D. Captain, M.C.,
A.U.S. Washington D.C.

IN the past 3 years, 10 women with adenocarcinoma of the uterus, comprising 0.5 per cent of the patients on the gynecologic service have been treated at Walter Reed General Hospital. These cases are presented without 5 year follow up for two reasons: residual carcinoma was found in 6 of the 7 uteri which had received enormous doses of radium by means of the hysterostat designed by one of us (M.F.) and the presence of ovarian metastasis in 3 patients emphasizes the necessity for oophorectomy as part of the treatment.

Recent reports have suggested that pan-hysterectomy with bilateral salpingo-oophorectomy should result in a 5 year arrest of 60 to 65 per cent of operable lesions (4, 11). The impression that the 5 year survival rate may be increased to 70 or 80 per cent by the use of preoperative radium followed by hysterectomy has been growing during the last 10 years. The majority of recent authors have advocated this combined method of treatment. Because small doses of radium in the order of 1,500 to 2,500 milligram hours have relatively little effect on adenocarcinoma of the uterus, conclusions drawn by authors who employed these small doses are of questionable value. The few reported cases treated with 4,000 or more milligram hours of radium are inadequate for a correct statistical evaluation of the combined method of treatment.

Corscaden (1944) reported 25 cases in which patients were treated with radium and hysterectomy in which the 5 year survival rate was 72 per cent. He recommended 3,000 to 4,500 milligram hours if given in one massive dose. Sheffey (1943) reported 30 cases in which patients were treated with

combined therapy in which there was 38.4 per cent survival after 5 years. Only 9 of the 30 patients received doses of 4,000 to 5,000 milligram hours. In his cases of patients treated by surgery alone, the 5 year survival rate was 18.1 per cent.

Ward (1942) reported 37 cases in which combined treatment had been used with 64.9 per cent 5 year survival as compared with 63 per cent in 27 cases in which surgery alone was used. The radium dose varied from 2,400 to 4,000 milligram hours, followed by post-operative x-ray therapy.

Heyman (8) in Sweden (1937) reported 5 year arrest of 78.5 per cent of 65 cases in which treatment consisted of hysterectomy followed by radium and x-ray therapy. In 1941 (9) he reported a series of 402 including inoperable cases in which patients were treated with radiation alone, with a 5 year survival rate of 40 per cent. Included in this group were 156 clinically operable cases in which patients were treated only by radiation and in which the 5 year survival rate was 48.7 per cent. He did not employ the combined treatment of radium followed by hysterectomy except in one subgroup of patients, who were operated on after radium therapy had failed. In this group the survival rate was 46 per cent. The usual radium dose was 3,000 milligram hours delivered in two applications of 1,500 milligram hours at an interval of 3 weeks.

Brindley (1941) reported 24 cases with 79 per cent 5 year survival. He used the combined treatment. The radium dose varied from 800 to 4,800 milligram hours, averaging 2,600 milligram hours.

Miller (1940) reported 34 cases in which treatment consisted of radiation followed by surgery. The 5 year survival rate was 70.5 per cent. Although he recommended pre-

From the Walter Reed General Hospital, Washington, D.C., and the Women's Surgical Section and Radiation Therapy Section of the Surgical Service and Pathology Section of the Laboratory Service.

operative x ray therapy only the exact number of patients so treated and the dose were not mentioned

Morton (1939) reported 18 cases in which the combined treatment produced a 66 per cent 5 year cure. Thirteen additional cases in which surgery alone was used had a 69 per cent 5 year survival rate. The dose of pre-operative radium was not specified

Healy and Brown (1939) reported 28 cases in which 3 000 to 4 000 milligram hours of radium was administered preceding hysterectomy. The 5 year survival rate was 79 per cent

Arneson (1936) treated 10 cases with radium followed by hysterectomy to obtain a 5 year survival rate of 90 per cent. The dose of radium varied from 1 600 to 4 000 milligram hours, 6 patients receiving more than 3 000 milligram hours

These published reports of a relatively small number of cases have been influential in determining the present trend toward combined therapy. The statistics in themselves are not conclusive. The recognized abilities of the authors however demand that their opinions be given careful consideration. Presumably, there are favorable clinical impressions of individual patients salvaged by the combined method which are not entirely reflected in the statistics

In 1934 Sampson warned that a straight radium tandem in the uterine cavity failed to irradiate the uterus homogeneously and that carcinoma localized in the cornu might be unaffected. In spite of his admonition the straight tandem continues to be widely used. Other methods of using radium in the uterus include multiple packing of loose capsules with strings attached or incorporation of capsules in a gauze pack (2). The capsules have been attached to wires (4, 5) in an attempt to fan out the radium. Several other devices have been designed (10, 16, 18)

RADIUM TECHNIQUE

The radium applicator which is called hysterostat was designed to achieve a more equable distribution of radiant energy to all parts of the uterus. Its construction was based on the following features

Fig. 1. Diagram illustrating intensity of radium energy distribution around platinum capsule. The greatest intensity is found along the side point A. The weakest intensity of radiation is located at point C which lies obliquely off the end of the capsule. A pencil beam of weak radiation comes directly off the end of capsule to point B (see Fig. 2)

1. Study of the distribution of radiation energy around a radium capsule with a wall thickness (filter) of 1 or 1.5 millimeter of platinum reveals certain data of utmost importance to successful use of radium in the uterus

a. The greatest intensity of radiation is found along the side of a radium capsule (point A, Fig. 1) due to a filtration factor and a distance factor. Most of the rays emanating from all points along the radium source travel obliquely through the metal wall of the capsule to reach point A. The longer path through the wall of the capsule which the oblique rays must traverse subjects them to increased filtration in the metal wall. However this increased filtration is at a minimum for point A as compared with all other points equidistant from the outer wall of the capsule (point C for example). In addition, the average of the distances which the rays traverse from each point along the radium source to reach point A along the side of the radium capsule is shorter than for point C or any other point equidistant from the wall of the capsule

b. The weakest intensity of radiation from a linear radium capsule is located at a point obliquely off the end of the capsule (C, Fig. 1) because the average distance which the rays, from each point along the radium source, travel is longer than for point A. Furthermore many of the rays traveling obliquely through the wall of the capsule to reach point C must traverse eight or more times the stated thickness of the metal wall before emerging from the capsule. Thus the high filtration considerably decreases the intensity of the total radiation reaching point C

c. Radiation coming directly off the end of a linear radium capsule to point B (Fig. 1) is filtered only with the minimum stated filter of 1 or 1.5 millimeters of platinum. This advantage is neutralized by the fact that the average distance which the rays traverse from each part of the radium source is the longest of all the average distances. As a result, a narrow pencil of increased

Fig. 2 Actual picture of radiation intensity distribution made by placing a radium capsule against an unexposed film suspended in air. The radium element source is centimeters long and the wall of the capsule is .5 millimeters of platinum. Note the great intensity of radiation along the side of the radium capsule, and the equally striking weakness of the radiation coming off the end of the capsule, with the exception of narrow pencil beam (arrow) in the long axis.

radiation intensity comes off the end of the capsule (see arrow Fig. 2)

d. The great intensity of radiation along the side of the radium capsule, and the equally striking weakness of the radiation coming off the end of the capsule are illustrated in Figure 2. These facts are significant when the tissue to be irradiated comes in direct contact with the radium sources, in the treatment of corpus carcinoma.

2. When several capsules are placed perpendicular to a surface the intensity of radiation reaching that surface will be relatively small. In Figure 3, although 2 capsules are pointed at the cornu, it receives less radiation than those parts of the uterine wall in direct contact with the sides of the capsules.

3. For effective radiation of the fundus of the uterus, one or more radium capsules must lie flat against it. Several tandems or individual capsules pointing at the fundus perpendicularly will not provide comparably effective radiation. The crosspiece of the hysterostat permits proper placement of radium against the fundus (Figs. 4 and 5) and can be adjusted to provide contact with a concave fundus (Fig. 12).

4. Studies of energy distribution around radium sources, according to the Paterson-Parker dosage system for gamma ray therapy¹⁴ indicate that radium sources should be placed peripherally around an area which is

Fig. 3 Self-exposed photograph made with hysterostat containing 6 radium capsules, as in Figure 5b. Hypothetical uterine canal is 7 centimeters long. Although two capsules are pointed at each cornu, the weakness of radiation intensity in the cornu is readily apparent. The fundal myometrium is effectively irradiated by the crosspiece. The midpoint of the triangle is irradiated by crossing from all the capsules, so that additional radium seems unnecessary.

to be homogeneously irradiated, within certain spatial limitations. The addition of multiple sources within the center of this area (packing a uterine cavity with multiple radium capsules) serves to increase the intensity of radiation within the center of a cavity where it is already high (Fig. 3).

5. The hysterostat is constructed of multiple sections which can be screwed together in the operating room after the contour of the uterus has been defined so as to produce a roughly triangular distribution of radium sources within the uterine cavity. Each section is the length of a single radium capsule. Sections in two angulations (150° and 165°) are provided so that a uterine cavity of almost any size or irregular configuration can be fitted (Figs. 5a, b, c). The crosspiece (Figs. 4 and 5) is so arranged that it can occupy four different predetermined angles in relation to

Fig. 4. The crosspiece. The handle end is on the left, the radium end on the right. The flange, *B*, is attached to knob only and slides into the limiting slots, *D*, in the revolving sleeve *C*. The flange must be pulled below the fixed guard, *F*, before the sleeve can be rotated. *E*, Tubular stem through which runs the central wire.

At the radium end of the crosspiece is the shell, *G*, which can be unscrewed and a radium capsule inserted. This can be made any desired length by adding extra straight or angular pieces. The shell is attached by a hinged joint, *I*, to the end of the tubular stem, *E*. The central wire emerging from the tubular stem is attached to one end of the shell by means of an axle joint *L*.

the supporting stem. Four side-pieces are provided but only two of them are needed except in unusually large uteri.

The sheaths which contain the radium capsules are constructed of monel metal tubing with a wall thickness of 0.4 millimeter which provides an ideal secondary filter. These sheaths can be constructed to contain radium capsules of different sizes. We have employed two sizes, 4 by 23 millimeters and 6 by 18 millimeters.

6 The radium dose which we employ has been arrived at by empirical means. Calculation of the distribution of the radium energy to various parts of the uterus in units of gamma roentgens has not yet proved to be of practical value in ascertaining the desired radium exposure of a particular uterus under treatment.

The individual capsules contain 10 or 15 milligrams radium with a primary filter of 1

Fig. 5. Crosspiece and lateral tandems arranged in 3 different hypothetical distributions. a, Arrangement of 4 capsules in a uterine cavity 5 centimeters long. One lateral tandem contains a 150 degree angle section. The other lateral tandem is angulated by bending the flat stem. b, Arrangement of 6 capsules in a uterine cavity 7 centimeters long. This has been accomplished by inserting an extra section into each lateral tandem. c, Arrangement for a large irregular uterine cavity. The additional 2 lateral tandems are available in case a large uterine cavity can accommodate them. Note that each arrangement of the applicators provides one radium capsule in the cervical canal.

or 1.5 millimeters platinum and a secondary filter of 0.4 millimeter of steel. A dose of 1 000 milligram hours per capsule is given when the uterus is normal in size. A small uterus with a cavity 5 centimeters long holding four capsules will receive a total dose of 4 000 milligram hours given in one treatment. If the uterus is larger and contains more radium capsules the individual dose per capsule is from 700 to 1 000 milligram hours. The total doses in this series ranged from 6 000 milligram hours to 12 480 milligram hours.

Generally when the uterus is larger than normal and the total dose is to exceed 5 000 milligram hours radium is given in two treatments at an interval of 7 to 10 days. The

Fig. 6 Case 1: Biopsy before x-ray therapy. This growth is classified as a moderately undifferentiated adenocarcinoma originating in the endocervical glands. The tendency to form lividula structura is clearly shown. $\times 63$.

uterine canal usually shrinks and its shape changes after the first treatment so that the radium must be rearranged for the second treatment.

This technique had been employed in 28 cases by one of us (M.F.) in civilian life prior to 1942. The radium exposures in half of

these ranged from 6,000 to 10,230 milligram hours. These cases will be the subject of a future publication.

Several other devices have been designed for the purpose of obtaining diffuse distribution of radium energy throughout the uterus. Schmitz using a Y shaped applicator administered doses up to 6,000 milligram hours. Kaplan employing a ring applicator administered doses ranging from 6,000 to 7,410 milligram hours.

CASE REPORTS

CASE 1: Moderately undifferentiated adenocarcinoma of the cervix, slightly advanced.

A moderately well nourished white female, aged 39 years, was admitted to the hospital September 4, 1944, complaining of intermenstrual bleeding for 3 months. She had one child aged 17 and had had one miscarriage 2 years ago. Menses were regular every 28 days, lasted 7 days, with moderate flow and no pain. Six weeks before admission the patient noted a mass protruding from the vaginal orifice, which disappeared when she lay down.

On examination, the abdomen was flat and soft, with no masses or tenderness. The vagina was normal. Protruding from the cervix was a hard, rounded mass, 5 centimeters in diameter with a red granular surface which bled easily. The uterus was of the usual size anterior and free. Ovaries were normal. There was no induration in the broad ligaments.

Fig. 7 Left, Case 1: Biopsy 8 days after x-ray treatment started (3 days after completion of tumor dose of 3,030 delivered over period of 5 days). There are slight to moderate radiation effects, predominantly nuclear hyperchromatism and to a less extent cytoplasmic vacuolization. $\times 70$.

Fig. 8. Case 1: Another area of section shown in Figure 7. Here the radiation effects are much more striking. $\times 70$.

Fig. 9. Case 1. Entire uterine cavity showing granulating endocervical surface at site of tumor. The upper portion of the corpus appears relatively normal.

Biopsy of the endocervical tumor showed moderately undifferentiated adenocarcinoma (Fig. 6). Supervoltage x-ray therapy was given with rays activated at 1,000,000 volts over a period of 15 days. The skin dose ranged from 1,000 r to 1,500 r to each of five skin portals. The tissue dose delivered to the tumor in the cervix was 3,030 r.

Three days later (18th day after initiation of treatment) the cervical tumor had shrunk about 20 per cent, and measured 4 centimeters in diameter. The uterine cavity was curetted and the tissue obtained was benign proliferative endometrium. The cervical tumor was excised with endothermy. A radium tandem composed of 3 platinum capsules totalling 60 milligrams of radium was introduced into the uterine cavity and three cork each of 15 milligrams radium were placed in the vagina about the cervix. A total dose of 8,000 milligram hours was given.

Microscopic examination of the cervical tumor (Figs. 7 and 8) revealed in response to 3,030 r extensive destruction of tumor cells. Those remaining showed moderate to marked changes predominantly nuclear alteration and to a lesser degree swelling and vacuolation of the cytoplasm.

Sixty-five days after radium abdominal panhysterectomy and bilateral salpingo-oophorectomy were performed the Richardson technique being used. The peritoneum and intestines were normal. No enlarged lymph nodes or induration were present. The uterus was small and atrophic (Fig. 9) as were

Fig. 10. Case 1. Section of cervix near external orifice showing nests of residual carcinoma deep in the wall. X140.

the tubes and ovaries. There were no adhesions. The postoperative course was entirely uneventful and the patient was discharged on the 18th day.

The excised uterus was examined microscopically and islands of residual carcinoma were seen in the endocervix near the external os (Fig. 10).

Five months after operation the patient was thin and complained of diarrhea and frequency of urination. There was moderate induration at the apex of the vagina with marked redness and yellowish discharge.

This case demonstrates that roentgen therapy can contribute effectively to the destruction of the undifferentiated forms of adenocarcinoma. On the other hand a large radium exposure (8,000 mgm hr.) failed to destroy all the tumor in the cervical myometrium.

CASE 2. Undifferentiated carcinoma of corpus uteri advanced.

This patient aged 61 years white was admitted on August 10, 1911 complaining of irregular vaginal bleeding for 6 months. Eighteen years previously she had received radium for a fibroid tumor of the uterus following which her menses ceased. She had 13 children.

The patient was somewhat obese and her blood pressure was 100/100. The cervix was moderate in size firm and closed. The uterus was of times normal size enlarged more to the left and freely movable. No axial masses or induration were detected.

At time of curettage the uterine canal measured 12.5 centimeters and contained a large amount of yellow friable tissue which proved to be undifferentiated adenocarcinoma on histologic examination (Fig. 11).

Fig. 6. Case . . . Biopsy before x ray therapy. This growth is classified as a moderately undifferentiated adenocarcinoma originating in the endocervical glands. The tendency to form alveolar structures is clearly shown. $\times 63$

uterine canal usually shrinks, and its shape changes after the first treatment so that the radium must be rearranged for the second treatment.

CASE REPORTS

CASE 1. Moderately undifferentiated adenocarcinoma of the cervix, slightly advanced.

A moderately well nourished white female aged 39 years was admitted to the hospital September 1, 1944, complaining of intermenstrual bleeding for 3 months. She had one child aged 17 and had had one miscarriage 2 years ago. Menses were regular every 28 days, lasted 7 days with moderate flow and no pain. Six weeks before admission the patient noted a mass protruding from the vaginal orifice, which disappeared when she lay down.

On examination the abdomen was flat and soft, with no masses or tenderness. The vagina was normal. Protruding from the cervix was a hard, rounded mass, 5 centimeters in diameter with a red granular surface which bled easily. The uterus was of the usual size, anterior and free. Ovaries were normal. There was no induration in the broad ligaments.

Fig. 7. Left, Case . . . Biopsy 8 days after x-ray treatment started (3 days after completion of tumor dose of 3,030 delivered over period of 5 days). There are slight to moderate radiation effects, predominantly nuclear hyperchromatism and to a less extent cytoplasmic swelling. $\times 70$.

Fig. 8. Case . . . Another area of section shown in Figure 7. Here the radiation effects are much more striking. $\times 70$.

Fig. 9. Case 1. Entire uterine cavity showing granulating endocervical surface at site of tumor. The upper portion of the corpus appears relatively normal.

Biopsy of the endocervical tumor showed moderately undifferentiated adenocarcinoma (Fig. 6). Supervoltage x-ray therapy was given with rays activated at 1,000,000 volts over a period of 15 days. The skin dose ranged from 1,000 r to 1,500 r to each of five skin portals. The tissue dose delivered to the tumor in the cervix was 3,030 r.

Three days later (18th day after initiation of treatment) the cervical tumor had shrunk about 20 per cent, and measured 4 centimeters in diameter. The uterine cavity was curetted and the tissue obtained was benign proliferative endometrium. The cervical tumor was excised with endothermy. A radium tandem composed of 3 platinum capsules totalling 60 milligrams of radium was introduced into the uterine cavity and three corks, each of 15 milligrams radium, were placed in the vagina about the cervix. A total dose of 8,000 milligram hours was given.

Microscopic examination of the cervical tumor (Figs. 7 and 8) revealed in response to 3,030 r extensive destruction of tumor cells. Those remaining showed moderate to marked changes predominantly nuclear alterations and to a lesser degree swelling and vacuolation of the cytoplasm.

Sixty-five days after radium abdominal pan-hysterectomy and bilateral salpingo-oophorectomy were performed the Richardson technique being used. The peritoneum and intestines were normal. No enlarged lymph nodes or induration were present. The uterus was small and atrophic (Fig. 9) as were

Fig. 10. Case 1. Section of cervix near external os showing nests of residual carcinoma deep in the wall $\times 130$.

the tubes and ovaries. There were no adhesions. The postoperative course was entirely uneventful and the patient was discharged on the 18th day.

The excised uterus was examined microscopically and islands of residual carcinoma were seen in the endocervix near the external os (Fig. 10).

Five months after operation, the patient was thin and complained of diarrhea and frequency of urination. There was moderate induration at the apex of the vagina with marked redness and yellowish discharge.

This case demonstrates that roentgen therapy can contribute effectively to the destruction of the undifferentiated forms of adenocarcinoma. On the other hand a large radium exposure (8,000 mgm hr.) failed to destroy all the tumor in the cervical myometrium.

CASE 2. Undifferentiated carcinoma of corpus uteri advanced.

This patient aged 6 years white was admitted on August 10, 1941, complaining of irregular vaginal bleeding for 9 months. Fifteen years previously she had received radium for a fibroid tumor of the uterus following which her menses ceased. She had had 3 children.

The patient was somewhat obese and her blood pressure was 100/100. The cervix was moderate in size, firm and closed. The uterus was four times normal size, enlarged more to the left and freely movable. No adnexal masses or induration were detected.

At time of curettage the uterine canal measured 12.5 centimeters and contained a large amount of yellow friable tissue which proved to be undifferentiated adenocarcinoma on histologic examination (Fig. 11).

Fig. 12. Case 2. Section of tumor before therapy showing an extremely undifferentiated carcinoma. The cells are compactly arranged in solid sheets with thin vascular trabeculae coursing throughout. $\times 63$.

The first radium treatment was given on August 18, 1944. By means of a three-piece hysterostat, 12 capsules of 10 milligrams each were inserted in triangular arrangement. The dose was 5,760 milligram hours (Fig. 12).

Fifteen days later another curettage was performed preparatory to the second radium treatment. The uterus had shrunk, the canal now measuring 9 centimeters. A large amount of yellow friable chiefly necrotic tissue was removed apparently from every portion of the corpus. Histologic examination of this tissue revealed considerable necrosis of the tumor cells, but some islands in the

Fig. 13. Case 2. Fragments of tumor 5 days after first radium treatment of 5,760 milligram hours. Moderate swelling and vacuolation of the cytoplasm are noted in areas shown. In other fields moderately differentiated papillary pattern was noted showing milder radiation effects. $\times 63$.

Fig. 14. Case 2. Roentgenograph of hysterostat containing 12 radium capsules. First radium treatment. Uterine canal 12.5 centimeters long, fundus 4.5 centimeters wide, irradiated with angular crosspiece.

undifferentiated portion of the tumor showed moderate swelling and vacuolation of the cytoplasm (Fig. 13). A few areas with a differentiated papillary pattern, not seen in the original biopsy, showed little effect from radiation.

With the three-piece hysterostat in a different, but still triangular arrangement, 12 capsules of 10 milligrams each were inserted in the uterus and a dose of 6,720 milligram hours was administered. The total exposure in the two treatments was 12,480 milligram hours.

Forty-four days after the second radium treatment, panhysterectomy and bilateral salpingo-oophorectomy were performed. The peritoneum and intestines appeared normal. There were no enlarged lymph nodes along the aorta or beneath the pelvic brim. The uterus was smaller than normal and freely movable; both tubes and ovaries were atrophic. In pulling up the uterus, moderate tension being used, the uterine veins were torn on each side and considerable bleeding ensued. The veins were rather small but thin-walled and friable. The parametrial tissues were moderately friable and sutures had a tendency to tear through the tissue. The postoperative course was uneventful and the patient was discharged on the 59th day.

Histologic examination revealed no evidence of residual tumor in the uterus, tubes, or ovaries. The

Fig. 14. Case 2. Uterus removed 44 days after second radium treatment. Total dose of 2 treatments 12,480 milligram hours. Note hemorrhagic and necrotic membrane completely covering the uterine cavity.

uterine cavity was lined with a thick hemorrhagic and necrotic membrane (Figs. 14 and 15).

Two months after operation the patient complained of increasing pain radiating down the back and side of the left leg and there later appeared marked edema of the leg. Six months after operation a firm fixed mass was felt in the lateral left lower abdomen above the inguinal region also edema of the left arm the cause of which had not yet manifested itself.

There are several distinctive features to this case. The first radium dose of 5,760 milligram hours which is ordinarily considered adequate for an undifferentiated tumor was ineffective in that moderate radiation effects were seen in the undifferentiated part of the tumor but only slight effects in the differentiated part. Shrinkage of the uterus brought the peripheral portions of the tumor closer to the radium sources during the second radium administration. The reduction in length of the uterine canal from 12.5 centimeters to 6.5 centimeters is noteworthy.

The total radium dose of 12,480 milligram hours is remarkably large and apparently effectively eradicated the uterine tumor.

CASE 3. Moderately undifferentiated adenocarcinoma corpus uteri, advanced.

This patient white aged 54 years was admitted March 10, 1944, complaining of continuous vaginal

bleeding for 2 months. Menses had been normal and regular until menopause April 1943. She had had 2 children.

The patient was in fair general condition. Bulging from the cervical canal which was dilated to about 4 centimeters was a grayish red granular friable tumor attached to the posterior and right lateral surface of the endocervix and extending well up into the uterus. The corpus was two and one half times normal size in midposition and free

Fig. 15. Case 3. Typical section of uterus shown in Figure 14. Note the organizing hemorrhagic membrane resting directly on the compact, atrophic myometrium. No residual carcinoma found in this case. X47.

Fig. 6. Case 3. Curettage before therapy showing typical arrangement of moderately undifferentiated adenocarcinoma. While there is a definite alveolar arrangement, in many areas the cells are grouped in compact masses with frequent abnormal mitoses. $\times 63$.

Posteriorly on the right side there was slight thickening. Biopsy revealed moderately undifferentiated adenocarcinoma (Fig. 16).

The presenting tumor was curetted. The canal was 9 centimeters long. A three-piece hysterostat containing 10 capsules of 15 milligrams of radium each was introduced into the uterine cavity (Fig. 17). A dose of 6,450 milligram hours was given.

The second radium treatment 8 days later consisted of the introduction of three corks containing a total of 55 milligrams of radium into the vagina against the cervix. The dose was 3,060 milligram hours. The total radium dose was 9,510 milligram hours.

Fig. 8. Case 3. Curettage 18 days after 6,450 milligram hours intrauterine radium showing one of several nests of residual, moderately undifferentiated carcinoma. There is slight radiation effect. $\times 63$.

Fig. 7. Case 3. Hysterostat containing radium capsules of 15 milligrams each. Uterine canal 9 centimeters long. Dose, 6,450 milligram hours.

Examination at the time of the second radium treatment showed the cervix to be of moderate size and closed. The uterus was twice normal size and free. There was definite thickening in the right uterosacral ligament. The uterine canal measured 9 centimeters. A large amount of yellow necrotic tissue was removed with the curette. Microscopic examination (Fig. 18) revealed islands of carcinoma showing slight radiation changes in the midst of considerable necrotic tissue.

Thirty-nine days after the vaginal radium treatment, panhysterectomy, bilateral salpingo-oophorectomy, and appendectomy were performed. Catheters had been placed in the ureters. The peritoneum and intestines appeared normal. One lymph node 2 centimeters in diameter was densely adherent to the aorta, 4 centimeters above the level of the umbilicus, and was not excised. One lymph node in the right hypogastric area, 1 centimeter in diameter, was excised. The uterus was slightly enlarged and irregular. The tubes were normal. The right ovary was 5 centimeters in diameter, slightly yellowish with a thickened capsule; the left ovary was atrophic. The right uterine vessels were ligated far laterally, laying the ureter to the side and taking the broad ligament tissues on the right. On the left, a conservative approach was made, going straight down along side the cervix. The patient was discharged 36 days after operation.

Histologic examination of the excised tissue revealed small islands of viable-appearing carcinoma.

Fig. 19. Case 3. Section of uterus removed 81 days after intrauterine dose of 6,450 milligram hours and vaginal dose of 3,960 milligram hours radium showing one of the residual neoplastic foci infiltrating the myometrium. The neoplastic cells form tubular structures and show moderate radiation effects. $\times 63$

infiltrating the superficial myometrium in 8 of 10 blocks taken from the corpus (Fig. 19). In the right ovary there was a cystic, metastatic lesion 3 by 3.5 centimeters (Fig. 20). The hypogastric lymph node showed hyperplasia but no carcinoma.

A postoperative course of roentgen therapy (1,000,000 volts) was given to the pelvis. The skin dose was 4,000 r to each of four pelvic portals. This delivered a tissue dose in each broad ligament of 3,160 r over a period of 73 days. Subsequently a second course of roentgen therapy was delivered through four portals crossfiring the preaortic node. The skin dose was $4 \times 3,000$ r; the tumor dose 5,400 r. There was no evidence that this node contained metastatic carcinoma. Eleven months after operation the patient felt well and was quite active.

The intrauterine radium dose was 6,540 milligram hours followed by a vaginal radium dose of 3,960 milligram hours. Nevertheless 81 days after the intrauterine radium treatment, the superficial layers of the myometrium were infiltrated by residual carcinoma which was differentiated in the form of tubular structures.

CASE 4. Moderately undifferentiated adenocarcinoma corpus uteri, early

This patient, aged 50 years white was admitted on July 23, 1944, complaining of moderate vaginal bleeding on one day July 16, 1944. Menopause had occurred 8 years previously. She had had 7 children the youngest then 23 years of age.

The patient was of moderate build. The vagina was thin with some varicosities. The cervix was small and reddened about the closed os. The uterus was small, in midposition and free there was

Fig. 20. Case 3. Metastatic papillary cystic lesion in right ovary lined with large polygonal and columnar cells showing bizarre nuclear changes. The pleomorphism and the nuclear alterations are probably the effects of radiation. $\times 45$

no adnexal mass or induration. The uterine canal measured 6.5 centimeters at the time of curettage. Many small pieces of grayish white tissue were removed.

Microscopic examination showed moderately undifferentiated adenocarcinoma (Fig. 21) generally forming large glandular structures but with occasional scattered compact groups of neoplastic cells and a moderate number of mitotic figures.

One week later radium was introduced into the uterine cavity with a 3 piece hysterostat that contained 6 capsules of 15 milligrams each. A total dose of 6,030 milligram hours was given. This represented a dose of 1,005 milligram hours per capsule.

Forty five days after the radium treatment, pan-hysterectomy and bilateral salpingo-oophorectomy were performed. The peritoneal surfaces and intestines appeared normal. No enlarged lymph nodes were felt along the aorta or under the brim of the pelvis. The uterus was small, the tubes and ovaries atrophic. The tissues of the broad ligaments, cardinal ligaments and vagina were friable and easily torn. The postoperative course was complicated by partial intestinal obstruction and an abscess in the abdominal incision. The patient was discharged 35 days after operation.

The uterine wall averaged from 1.5 to 2 centimeters in thickness and the cavity was lined throughout with a creamy yellowish green necrotic membrane, 1 to 2 millimeters thick. In 4 of 7 blocks residual carcinoma in the superficial myometrium formed large glandular structures with an occasional island of undifferentiated cells showing moderate swelling of the cytoplasm (Fig. 22). In other areas, deep in the myometrium were seen numerous small spaces some partially lined with neoplastic cells of bizarre form.

Fig. 2. Case 4. Biopsy before radium showing moderately undifferentiated adenocarcinoma. In other fields more solid medullary arrangement of the cells was seen similar to that noted along one edge of the photomicrograph. $\times 63$.

Five months after operation the patient felt well and was fairly active. There were no masses or tenderness in the abdomen, and the incision was well healed. The vagina was slightly thickened at the apex. The broad ligaments were soft.

CASE 5. Undifferentiated adenocarcinoma of corpus uteri advanced.

This patient, aged 50 years, white, was admitted on August 31, 1943, complaining of brownish vaginal discharge daily for a year. She continued to menstruate regularly every 28 to 30 days. The flow was moderate, without pain, and lasted 4 days. She had 3 children, the youngest 23 years old.

Examination showed a well-nourished patient. The vagina was normal. The cervix was of moderate size with two minute polyps on the posterior lip. The uterus was twice normal size, irregular in outline anterior and free. The right ovary contained a small cyst 4 centimeters in diameter; the left ovary was atrophic. There was no induration in the pelvis.

Under anesthesia, the polyps were excised. The uterine canal measured 9 centimeters. The cavity was gently curetted. A large amount of friable granular grayish yellow tissue was obtained, apparently from every part of the corpus. Microscopic examination showed the cervical polyps to be benign; the endometrial tissue was for the most part undifferentiated adenocarcinoma (Fig. 23) while in a few fragments, the neoplastic cells were differentiating into glandular structures (Fig. 24).

Intracavity radium was administered in a 13 piece hysterostat, containing 10 capsules of 15 milligrams each (Fig. 25). The uterine cavity was large, the canal being 9 centimeters long, and the fundus 3.5 centimeters wide. For extraneous reasons a dose of 7,000 milligram hours was given, instead of the dose of 10,000 milligram hours which had originally been contemplated.

Fig. 22. a, left, Case 4. Uterus removed 45 days after 6,050 milligram hours radium. The diffuse pseudodiphtheritic lining membrane demonstrates the homogeneity of the radiation, and the probable extensive involvement of the entire uterine cavity by the original tumor. b, Residual neoplastic glands in superficial myometrium of corpus. Note the compact undifferentiated masses of neoplastic cells. $\times 70$.

Fig. 23. Case 5. Curettage before therapy showing complete undifferentiation present in parts of the tumor $\times 63$

Fig. 24. Case 5. Section of another fragment showing a definite tendency of the cells to form glandular structures. Compare with Figure 23 $\times 63$

Thirty-eight days after the radium treatment panhysterectomy and bilateral salpingo-oophorectomy were performed. The peritoneum and intestines were normal. No enlarged aortic or hypogastric lymph nodes were palpable. The uterus was slightly enlarged and free. The tubes and ovaries were atrophic. The cardinal ligaments and vaginal tissues were slightly edematous and felt fragile but no technical difficulty was encountered. The postoperative course was uneventful, and the patient was discharged after 23 days.

The cavity of the uterus was somewhat expanded with the canal measuring 7.5 centimeters (Fig. 26). Extending upward from the internal os was a pseudodiphtheritic membrane 3 by 4 centimeters in diameter and 3 to 4 millimeters thick. The upper posterior wall of the corpus was covered with a hemorrhagic membrane. Sections taken through the lower portions of the corpus revealed extensive carcinoma deep in the myometrium the surface being covered with the thick pseudodiphtheritic membrane. Similar carcinoma infiltrating the myometrium was found in sections from each cornu, occurring for the most part as infiltrating sheets of cells, with little tendency to form alveolar structures. The effects of irradiation were mild to moderate, and included slight swelling of the cytoplasm and the presence of a moderate number of bizarre nuclear forms (Fig. 27).

Seventeen months after operation, the patient felt better than she had in years, and had gained 15 pounds. The abdomen was soft. The vagina was thin and pale, somewhat shortened, well healed and with no residual thickening. The broad and uterosacral ligaments showed no induration.

This is a case of predominantly undifferentiated carcinoma similar to that in Case 2 in which a radium exposure of 7 000 milligram

hours failed to destroy the carcinoma completely.

CASE 6 Moderately differentiated carcinoma of corpus uteri moderately advanced

This patient aged 35 years white was admitted on December 31, 1944 complaining of vaginal bleeding which had continued for 18 months. Menarche occurred at 14 with intermittent menses until she was 16 when they ceased completely. In August, 1943 when the patient was 33 vaginal spotting began. After February 1944 bleeding became almost constant. She had had dyspnea on exertion since youth.

Fig. 25. Case 5. Hysterostat containing 10 radium capsules of 15 milligrams each. Uterine canal measured 9 centimeters long; fundus measured 3.5 centimeters wide. Crosspiece contained two capsules.

Fig. 26. Case 5. Uterus removed 38 days after 7,000 milligram hours of radium. Note the thick necrotic membrane covering the endometrial surface except for a triangular area on the posterior wall not covered by the hysterostat.

The patient was slender. Mitral stenosis with cardiac insufficiency was evident. The cervix was rather small, the os slightly dilated with a minute polyp high in the canal. The uterus was anterior slightly enlarged, symmetrical, and freely movable. Both ovaries were normal in size and were free.

At time of curettage the uterine canal measured 8 centimeters. A large amount of friable, yellowish tissue was obtained apparently from every portion of the interior of the uterus. Intracavity radium was administered with a 3 piece hysterostat con-

taining 7 capsules of 10 milligrams of radium each. A total dose of 7,000 milligram hours was given. Microscopic examination of the endometrium revealed moderately differentiated, infiltrating adenocarcinoma (Fig. 28).

Fifty five days after treatment, panhysterectomy and bilateral salpingo-oophorectomy were performed. The peritoneum and intestines appeared normal. There were no enlarged aortic or hypogastric lymph nodes. The uterus as small as moderately atrophic, both tubes and ovaries were atrophic. There was no technical difficulty at operation. The excised uterus (Fig. 29) was small and firm with a narrow tubular canal, approximately 1 centimeter in diameter and 6 centimeters long. The walls of the cavity were lined with firm red granulations. There was no pseudodiplothermic membrane. Microscopic examination showed, in 3 of 6 blocks, neoplastic glands infiltrating the endometrium. The effect of irradiation on the cells lining the alveoli was insignificant (Fig. 30).

The postoperative course was complicated by prolonged diarrhea and painful frequent micturition. After 2 months, the tissues at the apex of the vagina separated and formed an ulcer 3 centimeters in diameter. There was induration around the ulcer particularly beneath the bladder.

The uterine cavity was not large, the radium distribution and dose (7,000 milligram hours) was adequate according to our own concept of dosage but there was residual carcinoma infiltrating the myometrium.

CASE 7. Moderately differentiated adenocarcinoma of corpus uteri, advanced.

Fig. 27. Case 5. One of the several foci of residual carcinoma in the uterus shown in Figure 26. Extensive deep infiltration was found, generally by sheets of cells showing little tendency to form alveolar structures. Note the slight swelling of the cytoplasm and many bizarre nuclear forms. $\times 45$.

Fig. 28. Case 6. Fragments removed at time of diagnostic curettage composed of moderately differentiated neoplastic glands infiltrating the myometrium. $\times 63$.

This patient aged 67 years white was admitted on August 15 1944 complaining of pink mucoid discharge for 18 months. The patient had four children, the youngest 22 years old. The menopause had occurred 20 years ago. One year ago 6 x ray treatments given elsewhere stopped the pinkish discharge for 4 months.

The patient was obese and had hypertension (220/110) and arteriosclerosis. There were no abdominal masses or tenderness. The mucous membrane of the atrophic vagina was red; the cervix was small, firm and red. The uterus was in midposition and two one half times normal size. No adnexal mass or induration was felt.

At time of curettage the uterine canal measured 8 centimeters. Microscopic examination of the tissue obtained revealed moderately differentiated infiltrating adenocarcinoma (Fig. 31).

One week later a 3 piece hysterostat was inserted containing 9 capsules of 10 milligrams radium each. The dose given at this first radium treatment was 4,500 milligram hours. Eight days later the patient developed pelvic cellulitis, and at this time there was moderate induration in the rectovaginal septum and marked induration in the left broad ligament. The temperature and discomfort gradually subsided and the patient was discharged. Persistent pelvic induration caused the second radium treatment to be deferred.

Seventy days after the first radium treatment the patient returned with no complaints and no bleeding. Penicillin was given prophylactically for 5 days. Under anesthesia the uterus was one and one-half times normal size and fairly movable. There were no palpable adnexal masses but there was some thickening in the left uterosacral ligament. The uterus was thoroughly curetted. The endometrium was scant and the interior of the uterus was quite rough to the curette. At this time the uterine

Fig. 30. Case 6. Uterus and adnexa 55 days after 7,000 milligram hours of radium. Note the small uterine cavity covered with a granulating membrane.

canal measured 6.5 centimeters. A 3 piece hysterostat containing 8 capsules of 10 milligrams radium each was inserted and a dose of 4,400 milligram hours given (Fig. 32). The postoperative course was uneventful.

Fig. 30. Case 6. Low power showing one of the several residual areas of carcinoma infiltrating the myometrium. $\times 56$.

Fig. 3. Case 7. Biopsy before therapy showing moderately differentiated adenocarcinoma infiltrating the myometrium. X63.

Curettage 75 days after the first treatment of 4,500 milligram hours dislodged only a few fragments of tissue; however, they consisted mostly of persistent adenocarcinoma infiltrating the myometrium and showing no demonstrable effects of irradiation.

Eight months after the first radium treatment the patient felt well except for occasional bearing down sensations in the lower abdomen. The uterus was smaller than normal; pelvic induration had diminished. Panhysterectomy and bilateral salpingo-oophorectomy were performed. The operative

Fig. 33. Case 7. Uterus 6 months after second radium treatment. Uterine canal now measures 4.5 centimeters long (original length 8 centimeters). Not the uterine cavity completely lined with shaggy necrotic membrane.

Fig. 32. Case 7. Second radium treatment. Uterine canal has shrunk to 6.5 centimeters in length and 4.5 to 7 centimeters in width. Hysterostat now carries 8 capsules of 50 milligrams each. Dose 4,160 milligram hours. Total dose, 9 treatments, 8,900 milligram hours.

procedure was complicated by numerous post-inflammatory adhesions. There was marked chronic salpingitis, with moderate induration of the ovaries, sacral and left cardinal ligaments fixing the uterus deep in the pelvis.

The uterus was small with a canal 4.5 centimeters long. The cavity was completely lined with

Fig. 34. Case 7. Section of uterus shown in Figure 33 with residual carcinoma deep in the myometrium. X1.

Fig. 35 Case 8. Fragments from diagnostic curettage made up entirely of solid masses of large polygonal neoplastic cells similar to the arrangement seen in Cases 2 and 5. In other areas the cells are differentiating into large glandular structures. Mitoses are numerous throughout with many abnormal forms. This is classified as a moderately undifferentiated adenocarcinoma. $\times 63$

Fig. 36 Case 8. Section of uterus removed without usual preoperative course of radium showing residual zone of carcinoma in only one of the multiple sections taken $\times 63$

shaggy membrane beneath which patchy areas of organization were seen. The myometrium was not significantly thinned and the vessels were prominent (Fig. 33). Microscopic examination of 14 serial, cross-section planes through the entire uterus revealed tumor in 2 sections of the midcorpus. The tumor was present as elongated glandular structures deep in the myometrium in one (Fig. 34) while in the other the neoplastic cells were arranged in a solid nest.

The patient received a total dose of 8,900 milligram hours intrauterine radium in 2 treatments which brought about shrinkage of the uterus and disappearance of the symptoms. The outlook for arrest without hysterectomy seemed hopeful. However the finding of residual tumor in the other cases had demonstrated the necessity of hysterectomy wherever possible. Therefore operation was performed in spite of hypertension, obesity, diabetes, advanced age, and residuals of pelvic inflammation.

Residual carcinoma was present 75 days after the first radium treatment of 4,500 milligram hours, a dose which is considered adequate by many operators. Five and one-half months after the second radium treatment of 4,400 milligram hours several small islands of residual cancer could still be found deep in the myometrium. They might have remained dormant during the rest of the pa-

tient's life span but their removal increased the possibilities of a cure.

CASE 8. Moderately undifferentiated adenocarcinoma early almost completely removed at original biopsy curettage surgical treatment only.

This patient, aged 39 years, white, was admitted to the hospital December 4, 1944. Menses had customarily lasted 4 days with moderate flow. However she had a prolonged menstrual period lasting 8 days in August and again in November and December, 1944. There was no intermenstrual bleeding.

The vagina appeared normal, the cervix was smooth, firm and closed. The corpus was small and free, the ovaries normal.

The uterus was curetted thoroughly and a moderate amount of soft grayish tissue was obtained. Microscopic examination revealed moderately undifferentiated adenocarcinoma (Fig. 35). Panhysterectomy and bilateral salpingo-oophorectomy were performed. There was no evidence of extension or metastasis. The uterus tubes and ovaries appeared normal.

The interior of the uterus seemed normal when inspected grossly but on microscopic examination one minute neoplastic focus was found, others apparently having been curetted away (Fig. 36).

The postoperative course was uneventful 3 months later the patient was well and showed no evidence of disease.

This is an early case of moderately undifferentiated adenocarcinoma of the uterus treated only by extirpation of the uterus tubes and ovaries. The curettage for biopsy almost completely removed the tumor.

TABLE I—SUMMARY OF CASES

Case No.	Duration Age symptoms	Type adenocarcinoma	Preoperative radiation	Interval radium to posthysterectomy	Pathology after operation	Follow up after last treatment
34	1 mo	Moderately undifferentiated (adenocarcinoma)	X-ray tumor dose 3050 14000 mgm. hr in uterus and vagina	66 days	Islands carcinoma endometrium	3 mo No recurrence
67	1 mo	Undifferentiated	2,480 mgm. hr	44 days	No carcinoma	10 mo Local per vaginal recurrence
54	1 mo	Moderately undifferentiated	0.4 mgm. h (4390 mgm. hr in uterine cavity 3050 mgm. h in vagina)	30 days	Islands carcinoma uterus and right ovary	14 mo No recurrence
20	1 mo	Moderately undifferentiated	6050 mgm. hr	43 days	Islands carcinoma uterus	20 mo No recurrence
20	1 mo	Undifferentiated	7000 mgm. hr	38 days	Islands carcinoma uterus	21 mo No recurrence
5	8 mo	Moderately differentiated	7000 mgm. hr	33 days	Islands carcinoma uterus	1 mo No recurrence
67	8 mo	Moderately differentiated	4000 mgm. hr	4 months	Islands carcinoma uterus	6 mo No recurrence
20	1 mo	Moderately undifferentiated	None	—	Superficial island carcinoma	4 mo No recurrence
58	Several yrs	Moderately differentiated	None	—	Advanced carcinoma uterus with metastases both ovaries	Died 4 mo metastases
45	0 mo	Moderately differentiated	None	—	Adenocarcinoma uterus with ovarian metastases	10 mo No recurrence

CASE 9. Moderately differentiated adenocarcinoma corpus uteri, advanced with metastasis to ovaries

This patient, aged 58 years, white was admitted on August 11, 1942 with a history of daily bloody spotting from the vagina for many years. Menses ceased at 40 years.

The patient weighed 200 pounds. Abdominal palpation revealed large masses rising from the pelvis to the level of the umbilicus. The cervix was high in the vagina, smooth and closed. The fundus could not be distinguished from the lower abdominal masses. There was no induration or fixation of the pelvic floor.

At operation the uterus was two and one half times normal size soft and nodular. Both ovaries formed large cystic lobulated tumors, 35 centimeters and 0 centimeters in diameter. The ovarian tumors fallopian tubes and supracervical portion of the uterus were excised with difficulty.

Microscopic examination revealed extensive infiltrating moderately differentiated adenocarcinoma of the uterus with bilateral ovarian metastases.

Sixteen days later radium was inserted into the cervix and vagina for a total dose of 3,600 milligram hours. An incomplete course of postoperative roentgen therapy was given elsewhere. Six months later the patient died with peritoneal carcinomatosis ascites and a large metastatic retroperitoneal tumor.

This patient is recorded as an instance of ovarian metastasis, the significance of which will be discussed later.

CASE 10. Adenocarcinoma corpus uteri, bilateral ovarian metastasis.

This patient, aged 45 years, white, had constant vaginal bleeding from July 1944 until January 1945, when a total hysterectomy was performed at another hospital, for adenocarcinoma of the uterus. On admission to this hospital in March 29, 1945, no pelvic masses were palpable. Because of the frequency of ovarian metastasis, the abdomen was reopened. Although no obvious metastasis was observed both tubes and ovaries were removed. Gross examination of the cut surface of the right ovary and microscopic examination revealed secondary adenocarcinoma.

This case demonstrates the necessity for oophorectomy as part of the routine treatment of adenocarcinoma of the uterus. The use of radium alone is attended by the danger of neglect of ovarian metastasis.

ANALYSIS OF CASES

In this series of 10 cases of adenocarcinoma of the uterus, 9 were moderately advanced or advanced but without induration of the pelvic ligaments, and were therefore considered operable. Carcinoma protruded from the cervical os in two uteri and ovarian metastasis was subsequently found in 3 patients. Microscopic examination revealed moderate differentiation (grade 2) in 4 cases, moderate im-

differentiation (grade 3) in 4 cases, and complete undifferentiation in 2 cases. This distribution is atypical in that most large series have shown the majority of cases to be differentiated adenocarcinoma.

In 7 of the 10 cases treatment with radium was followed by panhysterectomy and bilateral salpingo-oophorectomy. The radium dose ranged from 6,030 to 12,480 milligram hours. Case 1 (the only instance of adenocarcinoma of the endocervix) had an x ray tumor dose of 3,030 r followed by 8,000 milligram hours of radium.

The size of the uterus was moderately or greatly reduced following radium. In Case 7 for example the uterine canal shrank in length from 8 to 4.5 centimeters. In Case 2 the uterine canal shrank from 12.5 centimeters to 6.5 centimeters.

The operative procedure was not unduly difficult except in Case 7 in which the residuals of pelvic inflammation complicated the operation. In every instance the parametrial tissues were somewhat sclerotic, with lack of resiliency and the sutures had to be tied with care. The uterine vessels seemed smaller than usual. In one instance the uterine veins were torn on each side as the uterus was being elevated. The Richardson conservative panhysterectomy technique was used in all except Case 3 in which a radical dissection was performed on the right side only because of slight preradiation thickening in the right uterosacral ligament.

Interesting was the finding of nests of apparently viable cancer cells in the superficial myometrium in 6 of the 7 excised uteri, with deeper extension in 3. The one uterus (Case 2) in which no residual carcinoma was found had a highly malignant undifferentiated adenocarcinoma which received 12,480 milligram hours of radium given in 2 exposures.

The location of residual carcinoma deep in the myometrium explains why probatory curettage performed several months after radium treatment in order to evaluate its effectiveness, may fail to extract the residual carcinoma.

It is possible that, after irradiation some of this residual carcinoma might not have manifested itself clinically for 5 years or longer.

However hysterectomy is necessary to complete eradication of the local tumor.

Reasons why the combined radium surgical treatment gives the best results according to the literature include (1) reduction of intra uterine infection preoperatively (2) reduction in size of the uterus simplifying the operative procedure (3) immobilization of cancer cells in the uterus reducing metastasis (4) sclerosing of lymphatics and blood vessels reducing metastasis (5) prevention of recurrence from operative spill in the vagina and abdominal incision and (6) favorable results borne out of statistical evidence.

Statistical evidence however is the only concrete information on the value of preoperative radiation. The available statistics discussed previously are based on small series varying from 10 to 37 cases. The 5 year arrests range from Sheffield's 38.4 per cent in 30 cases to Arneson's 90 per cent in 10 cases. Series of as many as 100 cases with uniform radium treatment in doses of 4,000 milligram hours or more should be available before the rôle of preoperative irradiation can be evaluated.

Preoperative roentgen therapy has been recommended by some notably Miller who emphasizes the additional destruction of tumor cells in the parametrium by this method. However the intensive x ray therapy necessary to give a lethal tumor dose may cause destructive changes in the bowel, and adhesions. The immediate postradium complications following the use of large doses were not serious. The one instance of acute pelvic cellulitis (Case 7) followed a relatively small radium dose of 4,500 milligram hours. However the later deleterious effects of intra uterine radium in the large doses employed in this series are not to be overlooked. Post operative hospitalization is lengthened. Recovery of vitality is often delayed for months. There may be delayed healing of the vaginal wound intermittent diarrhea, and frequency of urination. If the eventual cure rate is increased these disadvantages can be disregarded.

One patient (Case 8) had undifferentiated adenocarcinoma for which many authors recommend preoperative radium. The short

history scant endometrium and small uterus indicated an early lesion. Hysterectomy was performed without preliminary radium. Three patients (Cases 3, 9 and 10) had metastasis in the ovary. This not uncommon incidence of ovarian metastasis is frequently overlooked in planning therapeutic procedures for adenocarcinoma of the uterus. It constitutes an important argument against the use of radium alone in the treatment of this disease. Preoperative radium cannot materially affect the metastatic lesion in the ovary. Consequent postradium hysterectomy should not be unduly delayed.

SUMMARY

Ten patients with adenocarcinoma of the uterus were treated in the past 3 years at Walter Reed General Hospital. Seven patients received unusually large doses of radium (6,030 7,000 7,000 8,000 8,900 10,410 12,480 milligram hours) followed by hysterectomy 38 days to 6 months later. Six of these 7 uteri showed residual carcinoma. The one case in which there was no remaining carcinoma after radium was an extensive undifferentiated tumor in a large uterus treated with 12,480 milligram hours radium. One patient with very early undifferentiated adenocarcinoma was treated with surgery alone. Three patients had ovarian metastasis.

CONCLUSION

1. This study suggests that radium alone will not completely eradicate adenocarcinoma of the uterus. Subsequent excision of uterus, tubes, and ovaries is necessary.

2. The exact rôle and specific indications for preoperative radium therapy have not yet been satisfactorily delineated.

PRACTICAL OBSERVATIONS ON THE COPPER SULFATE METHOD FOR DETERMINING THE SPECIFIC GRAVITIES OF WHOLE BLOOD AND SERUM

ERNEST E. MUIRHEAD MD Lieutenant MC USNR M H GROW MD
Lieutenant MC, USNR Dallas, Texas and ALBERT T WALKER
MD FACS Captain MC USN Washington DC

THE clinical significance of the measurement of the specific gravities of whole blood and plasma or serum has been discussed by Barbour and Hamilton Weech *et al* Scudder Kagan Ashworth and Adams (1) Gray and Elliot Phillips *et al* Technical complications have at times offered impediments to the routine clinical application of several methods particularly in a military sense The authors of the copper sulfate technique (Phillips Van Slyke Dale Emerson Hamilton and Archibald) point out that this is a technically simple quickly conducted procedure which maintains a sufficient degree of accuracy under the usual variable circumstances to give it much clinical applicability In the present communication it is proposed to present additional evidence in support of the practical use of the copper sulfate values of whole blood and serum specific gravities

METHODS

The copper sulfate solutions were prepared as outlined by Phillips and co-workers. The stock solutions (specific gravity 1.1) were checked periodically by pycnometric procedures At times when solutions were prepared aboard ship pycnometry was not possible and the fresh standard solutions were checked via a series of normal samples with previously pycnometrically checked solutions. It was possible at other times to compare our solutions with those prepared by Army laboratory facilities ashore The constancy of checks established much confidence in the technique.

This work was commenced at the suggestion of and progressed under the direction of the senior author, Fleet Medical Officer Sea Commander Allied Naval Forces, Southwest Pacific Area.

Altogether 16 different batches of the stock solution were used in preparing the various standard sets used in the observations

For the actual determination the following procedure was used throughout venous blood was collected in a dry syringe (5 to 20 cc capacity) while stasis was limited as much as possible and drops from the syringe tip before clotting occurred were used for measuring the blood specific gravity the remainder of the blood was allowed to clot in a test tube spun in a centrifuge and the specific gravity of the serum was determined with the aid of a medicine dropper

The Sahli hemoglobin measurements were conducted first with daylight then with artificial light as background for color matching 14.5 grams per cent were considered as 100 per cent normal The red blood cell counts were done with routine type of equipment 10 squares being counted on each occasion

NORMAL VALUES

The normal series were taken from inactive normal healthy Army and Navy personnel (males) most of whom had been established in staging areas at sea level in tropical localities for weeks to months The samples were taken throughout the day prior to which time the individuals had been ambulatory for varying intervals

The frequency distribution of the whole blood specific gravity values on 577 different individuals is given in Table I The following features of these data are emphasized The over all range is 1.052 to 1.064 with only one value falling in each of these extremes the arithmetic mean value 1.0581 the standard deviation (σ) is 0.0019 the mean $\pm 2\sigma$ equals 1.0543 to 1.0619

The frequency distribution for the serum values on 574 of the above 577 samples is also given in Table I. The range for these values is 1.024 to 1.030 with only one value occurring below 1.025; the mean is 1.0273, the σ equals 0.0013; the mean $\pm 2\sigma$ equals 1.0247 to 1.0299.

These normal values have been taken as the basis for evaluating values obtained from subjects under various abnormal states in tropical zones (New Guinea to the Philippine Islands). It has been considered safe to state that blood specific gravity values by this technique outside of the range of 1.0543 to 1.0619 (mean $\pm 2\sigma$) are significant in denoting red blood cell dilution or concentration beyond normal limits. By the same token serum specific gravity readings outside of the range 1.0247 to 1.0299 have been considered significant in denoting dilution or concentration of the serum proteins beyond normal limits.¹

SPECIFIC GRAVITY VALUES RED CELL COUNT HEMOGLOBIN CONCENTRATION (SAHLI) COMPARISON ON NORMALS

It will be noted in Table II that the Sahli hemoglobin concentration as read against artificial light averaged about 0.8 per cent higher figures than the comparisons read against daylight.

All three of these values (specific gravity of blood hemoglobin concentration red blood cell count) depend mainly on the concentration of red cells per unit of blood for their level and so long as the methods of determination are reasonably correct one expects a satisfactory correlation between the values. The correlation obtained by the routine measures as demonstrated in Table II seems satisfactory, close and resembles similar correlations presented by Ashworth and Adams (1) and by Gray and Elliot utilizing other specific gravity and hemoglobin methods.

¹Significance is being given these ranges, means and deviations mainly because significance has been given to findings from similar and related procedures on such inactive normals. He had been ambulatory were compared with patients. He was of accuracy of stretcher type. Yet should be mentioned the physiologists point out that the plasma volume is somewhat lower in the erect posture than during recumbency due to the escape of type of fluid from the circulation which tends to concentrate both the red cells and the serum proteins (4). The study of Ferrer and Berlier demonstrating lowering of the serum protein concentration during the recumbency of sleep can be taken as additional elaboration of this concept.

TABLE I.—FREQUENCY DISTRIBUTION OF WHOLE BLOOD AND SERUM SPECIFIC GRAVITIES ON NORMALS.

Blood		Serum	
Sp. gr.	Frequency	Sp. gr.	Frequency
1.051	0	1.021	0
1.052		1.024	1
1.053	3	1.025	10
1.054	13	1.0255	10
1.055	35	1.026	4
1.056	60	1.0265	11
1.057	94	1.027	12
1.058	122	1.0273	51
1.059	68	1.028	20
1.060	86	1.0285	10
1.061	13	1.029	10
1.062	15	1.030	10
1.063	3	1.03	
1.064			
1.065	0		
Total	577	Total	574

The whole blood values are entirely symmetrical. The lower boundary of the "half" values in serum series is considered due to the presence of which encompasses whole values 1 or less, the tendency toward the whole values where the drop of serum acts as having no gravity between the half and the whole values.

VARIATIONS IN SPECIFIC GRAVITY VALUES IN NORMAL SUBJECTS INDUCED BY VARIOUS SOLUTIONS ADMINISTERED INTRAVENOUSLY

The variations in the specific gravities of whole blood and serum samples from normal subjects over a 24 hour period effected by substantial volumes of physiologic saline solution, normal human plasma, concentrated human plasma (four fold concentration) and concentrated human albumin (25 grams per cent) given intravenously were observed. The results are presented in Figure 1 which also contains similar observations following a comparable volume of whole blood given a subject with slight hemodilution.

Considering that the specific gravity of whole blood is due mainly to the concentration of red cells and that the serum specific gravity is due mainly to the concentration of the proteins, certain observations are evident. Saline, normal plasma, concentrated plasma and concentrated albumin all gave rise to dilution of the recipient's red cells. Following the latter three solutions this dilution remained evident until 12 to 24 hours had passed when preinfusion levels were reached. For saline the dilution was evanescent and a preinfusion level was noted 90 minutes after the infusion. The protein-containing solutions (normal plasma, concentrated plasma, concentrated

Abbreviations: Sp. gr. specific gravity; Hgb. chart, hemoglobin concentration as obtained from the Phillips chart per cent normal; hemo normal is taken as 14.5 grams per cent; Rbc. mill. red cell count expressed in millions, average.

bumin) produced little change in the serum protein concentration. Conversely saline effected a marked drop in the protein concentration which returned to preinfusion levels only after some 6 hours had elapsed. Blood given to a subject with specific gravity values slightly below normal caused an elevation in the red cell concentration the continuation of which must have become augmented by red cell production and liberation from active bone marrow areas. Little change occurred in the serum protein concentration from this infused volume of blood.

ISOLATED CASES ILLUSTRATING THE CLINICAL APPLICATION OF COPPER SULFATE SPECIFIC GRAVITY VALUES

The isolated cases used in demonstrating the clinical application of the specific gravity

values were all battle casualties occurring in various engagements during the recent Philippine campaign. At present the emphasis is placed mainly on the specific gravity studies as they deviate from the normal. A correlation of such studies with other aspects of casualty care, as types and volume of intravenous solutions used, types of cases, response to therapy—with main consideration of the shock state—will be presented later in a compilation of over 300 closely observed cases out of some 5,000 casualties handled by our medical facility (16).

HEMORRHAGE

It has long been emphasized that the loss of whole blood from the circulation is followed by dilution of the remaining red cells. Whether there is dilution of the serum (or plasma) pro-

Fig. 1. A demonstration of the changes in the specific gravities of whole blood and serum induced on normal subjects by various commonly used intravenous fluids. Comparable volumes were used. The normal plasma, concentrated plasma, concentrated albumin solution each contained approximately 75 grams of proteins. The blood was diluted about 1 to 5 with citrate-dextrose anticoagulant preservative solution. The time interval for the infusion is designated at the lower left corner. The solid lines represent whole blood specific gravities, the broken lines serum specific gravities.

teins over a sustained period seems to depend on several factors as the extent of blood loss, the interval of time before a determination is

made, the state of the protein stores, the demands on the protein stores by other complications, etc. The hemodilution commences

7.5	0.51	0.573	17.5	7.0		Pr Satisfactory

The grams of calcium gluconate were given in doses between each liter of blood to prevent tetany due to the citrate in the blood.

The same scheme will be used on all subsequent tables. The zero hour represents the first time the patient was seen and appraised; Hgb. chart and ser. prot. chart represent the hemoglobin concentration in grams per cent and the serum protein concentration in grams per cent as taken from the Phillips and Associates chart; various intravenous fluids are abbreviated as follows: pl., normal plasma; conc. pl., concentrated plasma (3-4 fold); c. alb., concentrated albumin solution (1 per cent); bl., distilled whole blood (1 to 4 and to 5 dilution); D-5, 5 per cent dextrose in normal saline solution; D-H, 5 per cent dextrose in distilled water; at the time the quantity of intravenous fluid is designated in the table the administration has just been completed, having been started usually at the time the previous specific gravities were taken.

early but when compensation by the subjects' own resources is all that induces it the final degree of dilution of the blood may not occur for 24 to 36 hours (7). During the first hour the dilution may not exceed 10 per cent (13); indeed in occasional patients with hemorrhagic hypotension it has been reported that there may be no dilution or actual concentration of the red cells (hemoconcentration) (6, 15). The administration of intravenous fluid not containing red cells particularly protein fluids as plasma or albumin solutions by their inherent properties accelerates the development of the final degree of hemodilution in hemorrhage cases (17).

The extent of the drop in blood specific gravity, the effect on the serum specific gravity, the state of the blood pressure, the clinical picture, the response to therapy (including the quantity and quality of the fluids used) are all important in estimating a case of acute blood-loss clinically. Examples demonstrating the value of specific gravity studies will be divided into the patient (1) suspected of having a substantial hemorrhage (2) with hemorrhage with embarrassment to the circulation and (3) with hemorrhage followed by volume compensation (acute hemorrhagic anemia).

Following is an instance of a patient suspected of having a substantial hemorrhage

CASE 1. This patient sustained multiple lacerations involving the skin and muscles of the upper extremities back and legs; there was no fracture. He was seen about 4 hours after the injury. 250 cubic centimeters of normal plasma had been given intravenously. The specific gravity values were 1.054 for blood, 1.026 for serum, the blood pressure was 120-80 millimeters, hemoglobin, the pulse rate was 100 beats per minute, but the patient was restless; confused; the pulse was weak. Following 1,000 cubic centimeters of normal plasma by vein there was obvious clinical improvement and 7.5 hours later the specific gravity figures were 1.050 and 1.026. After 22 to 23 hours the specific gravities leveled off at 1.051 to 1.027, slightly lower than the normal range for the blood value.

The patient sustained injuries conducive to blood loss, the extent of which was unknown. The clinical improvement with plasma alone plus a stabilization of the blood specific gravity at levels only slightly below normal indicated a blood loss not of extreme proportions. Without the concentration studies complete confidence in this case would have been more difficult.

Hemorrhage with moderate to severe circulatory embarrassment. We are considering here the patient with tendency toward a lowered arterial pressure, weak pulse, restlessness or disorientation to coma, lowered urinary output, paleness with or without sweating, etc. following types of injury conducive to copious hemorrhages. Some have termed the state hemorrhagic shock (5); others prefer hemorrhagic hypotension applied to recoverable cases (22) while others object to applying the terms shock where simple hemorrhage appears to be the main complication (14). The demonstration of hemodilution by the copper sulfate method is our main concern at present.

CASE 2 The first patient sustained severe injuries to the right leg following an attack on one of our ships. He was seen some 8 hours later at which time there were clinical indications of severe circulatory embarrassment: pulse too weak to be definitely palpable, semiconscious, marked pallor, lowered skin temperature. The right leg was severely crushed and mangled and it was learned that the individual had been in the water (sea) some 45 minutes without a tourniquet before being rescued. Table III demonstrates marked hemodilution. Following the administration of concentrated albumin and whole blood (amount in table) there was much improvement, the right leg was amputated, additional blood and plasma were given and later the specific gravity of blood was only slightly below the normal range. The patient did well subsequently.

CASE 3 The second patient was seen 3 to 4 hours following the injuries, extensive shrapnel lacerations of the face, right arm, and right leg. The patient was weak, pale, cold, the pulse quite weak, the blood pressure 102/68. After 1100 cubic centimeters of whole blood there was much improvement but a total of 2,800 cubic centimeters of blood was required to elevate both blood and serum specific gravity values to near the normal ranges (Table IV). The patient improved and progressed nicely.

Hemorrhage with acute posthemorrhagic anemia This group includes the patients seen 2 to 3 days or longer following injuries producing blood loss and the final degree of hemodilution has been reached. At this time it is considered that an insufficient interval has elapsed in many cases for dietary and bone marrow depressing complications to affect the blood picture appreciably.

CASE 4. The first illustrative patient (Table V) was seen 2 days following the injury (gunshot wound

TABLE VI.—SPECIFIC GRAVITY VALUES IN

with abdominal perforation, injury to left kidney and spleen, emergency splenectomy.) The dilution of the red cells was prominent and it required 2750 cubic centimeters of whole blood given in 48 hours time to elevate the specific gravity to normal levels.

CASE 5 The second patient was likewise seen 2 days following the injury by shell fragments causing laceration of the abdominal wall and perineum, perforation of the urinary bladder and rectum. On this occasion, there was dilution of both red cells and serum proteins (Table VI). The specific gravity values returned to normal range following 4,400 cubic centimeters of blood.

BURNS

Early phase Here is included burn cases seen while there is increased permeability of capillaries giving rise to a decrease in the plasma volume and hemoconcentration (shock period).

CASE 6 The first patient was seen 8 hours following the burn (Table VII). He had received plasma intravenously prior to this time but the amount was not known. When seen there was pronounced concentration of the red cells as demonstrated by a blood specific gravity value well above the normal range. The extent of capillary damage and plasma volume depletion can be appreciated by the volume of protein solution required to lower the blood specific gravity to normal levels.

CASE 7 The second case is presented mainly because it reveals the highest blood specific gravity values seen. This patient came under our observation 4 hours after severe burns involving the entire body surface with the exception of about 50 per cent of the left arm and the area covered by swimming trunks. The left leg was parched, the foot blue and cold. The patient was in deep shock, unconscious, the pulse not palpable, the skin about the genitalia cold and prominent with bluish-gray mottling. The first blood samples (from femoral veins) were exceedingly thick and almost black in color (specific

gravity 1.074) The tremendous quantities of albumin and plasma required to control the hemoconcentration are given in Table VIII. The blood specific gravity returned to normal levels, the left foot became warm and pink, the patient regained consciousness. At no time was there evidence of pulmonary edema or right sided cardiac embarrassment (no venous engorgement). The first urinal specimen contained four plus albumin, red cells and casts. As soon as consciousness began to appear, troublesome retching with vomiting of blood began. The patient was reported to have died later aboard the evacuating ship. (With the patient so severely burned and without treatment for so long and in such extreme shock, it was decided to cope with the hemoconcentration regardless of the volumes needed so long as venous congestion or pulmonary edema did not become evident, as this approach seemed to give him his best chance.)

Later phase This group includes burn cases seen after 72 hours when anemia and hypoproteinemia begin to be prominent.

CASE 8 This patient had sustained burns involving about 40 per cent of the body surface of second and third degree types 5 days before. Plasma had been administered; the amount was not known. On admission the blood-serum specific gravities were 1.047 to 1.019. Following 500 cubic centimeters of concentrated albumin solution (75 grams albumin) 500 cubic centimeters of normal plasma and 1,100 cubic centimeters of citrated blood during the first day the specific gravity values became 1.045 to 1.0215. An additional 1,100 cubic centimeters of citrated blood were given and progress was being made in correcting the anemia hypoproteinemia complications when the patient was transferred for evacuation.

ANEMIA

An opportunity for the observation of specific gravity values in the anemia of malnutrition was afforded by a comparison of findings in a group of Javanese held by the Japanese as prisoners and utilized as laborers in Noemfoor

Island (Geelvink Bay New Guinea) and the findings on their captors, members of the Japanese Imperial Army (Table IX). The Javanese were a group of miserable looking individuals markedly emaciated ('skin and bones' appearance) many too weak to walk, several displayed large tropical ulcers on the lower extremities. Through interpreters they gave the now stereotyped story of starvation in the midst of adequate food supplies and overwork impelled by brutal treatment. In

Artificial light as background. Amounts of plasma given were too small to effect significant changes in serum protein levels.

the same location the Japanese were robust and well fed. In the captives the specific gravity values were indicative of severe anemia and hypoproteinemia while in the Japanese captors the values were within the normal range. A correlation with the Sahli hemoglobin values was also obtained. Blood and plasma infusions were given to some of these patients but the amounts were too small to alter appreciably the specific gravity values.

The treatment of anemia is demonstrated in a patient with malaria

CASE 9. This person had not felt well for weeks and had been very ill for about 10 days prior to admission. An extraordinarily heavy infestation with *plasmodium falciparum* was noted on thick and thin blood smears. The patient was comatose and displayed a dry tongue and some loss of skin turgor. The dietary intake had been poor. The specific gravities (blood and serum) were 1.041 to 1.042 indicative of prominent anemia and hypoproteinemia. Following 1,000 cubic centimeters 5 per cent dextrose in saline, 1,000 cubic centimeters normal plasma 1,000 cubic centimeters citrated blood (21 1/2 hours after admission) the specific gravity figures were 1.047 to 1.043. An additional 1,500 cubic centimeters of citrated blood and 1,000 cubic centimeters of normal plasma were given (30 1/2 hours after admission) and 16 hours later the specific gravities were 1.050 to 1.053. At 59 hours the values were 1.051 to 1.0345. The patient improved markedly. The transfusions seemed to be a definite adjunct to the quinine and atabrine therapy in this case.

DEHYDRATION

If one considers that the clinical signs of dehydration (extracellular type with or without intracellular dehydration) are reliable then serious grades of dehydration have not been encountered as frequently in the wounded who have access to water as was expected. The clinical signs used include the urinary output and the specific gravity of the urine dryness of the mouth and skin thirst as expressed by the patient, loss of skin turgor and elevation of the specific gravity values of blood and serum. Of course the majority of the patients seen had sustained wounds of the extremities with or without fractures and could and would take sufficient water by mouth. Abdominal cases (intestinal perforation obstruction colostomy fistula cases) naturally presented more of a strict water

salt balance problem. One such case is presented.

CASE 10. This patient was seen 12 to 14 hours following the injury, shrapnel perforation of the abdomen. A loop of bowel and the surface of the urinary bladder had been injured. An emergency operation had been performed the bladder repaired and the loop of intestine brought to the surface (marsupialized). The loop had broken down and produced a fistula.

On admission the patient exhibited signs of severe circulatory embarrassment (shock) coma with periods of restlessness, pulse very weak, blood pressure 90/60 millimeters hemoglobin, pale, sweating, veins inconspicuous. The specific gravity values (blood—serum) were 1.058 to 1.0375, within the normal range. The shock was treated with citrated blood (1,600 c.c.) and normal saline (1,000 c.c.) by vein. There was definite clinical improvement, consciousness was regained, the blood pressure reached 100/75, the pulse was strong and regular but the patient had a ravenous thirst. There was loss of skin turgor and the urinary output was negligible. At this time (7 hours after admission) the specific gravity figures were 1.063 to 1.058, an elevation of the blood value, which indicated a moderate concentration. One liter of 5 per cent dextrose in saline and 250 cubic centimeters of normal plasma lowered the specific gravity value of blood to 1.053 (19 hours after admission) but it returned to an elevated value (1.061 to 1.058 by 37 hours after admission). At this time 2,000 cubic centimeters of dextrose-saline and 500 cubic centimeters of normal plasma were given and the values again dropped to 1.057 to 1.0375 at 41 hours. After an additional 500 cubic centimeters of normal plasma the values were 1.054 to 1.025. The patient was much improved, quiet but continued to ask for large quantities of water. The bowel continued to discharge copious quantities of fluid. Additional saline and plasma (1,000 c.c. and 500 c.c.) were given to replace that lost through the fistulous opening. After transfer this patient was reported to have done well.

Intravenous protein feeding. When plasma solutions are administered by vein largely for the dietary value of the contained proteins, specific gravity values may be of use. Should the patient be receiving 1,000 to 2,000 cubic centimeters of normal plasma daily (60 to 120 grams proteins) and no significant alterations are noted in the concentration values from day to day then one has a good idea that the administered solids and fluids are being utilized. A case in point was a patient with acute catarrhal jaundice and initial specific gravity values of 1.052 to 1.023. Eleven and one-half hours after 1,250 cubic centimeters of normal

plasma were given the values were 1.050 to 1.0255. An additional 1.250 cubic centimeters of normal plasma were given and later the specific gravities were 1.052 to 1.027.

EVALUATION OF STUDY

This study was begun by establishing normal values of whole venous blood and serum specific gravities for males of military age at sea level in a tropical climate. Then the ranges means and standard deviations were obtained. Significance was given to values outside of the range obtained by the mean $\pm 2\sigma$.

A comparison of the blood specific gravity values, the hemoglobin concentration as measured by Sahli's method and the red blood cell count gave a correlation similar to that obtained by Ashworth and Adams (1). Alterations in the specific gravity values as produced by various solutions given by vein gave results similar to results in other studies (2, 9, 10, 11).

Illustrations of the copper sulfate procedure as applied to the care of various types of abnormalities seen in battle casualties were presented. These concentration studies (specific gravity of blood and serum) were of great value in demonstrating trends in the make up of the circulating blood (hemodilution, hemoglobin concentration, anemia, hypoproteinemia, etc.) and to a great extent in demonstrating the severity of trends. In conjunction with the clinical picture (history, physical examination, etc.) the blood pressure level and the response to therapy they formed a valuable asset in the appraisal and therapy of the wounded.

CONCLUSION

The copper sulfate method for determining the specific gravities of blood and serum can be used to great advantage in the appraisal and treatment of various surgical conditions. Additional evidence supporting this conclusion has been presented. The method is of par-

ticular value in military use when several factors as the sudden arrival of large numbers of wounded men, the necessity of rapid decisions concerning the shock state, the appraisal of patients before anesthesia and operative procedures are instituted, the need for medical judgment during attacks by the enemy, make its simplicity, speed, degree of accuracy and instant applicability most desirable.

LUMBAR APPENDICITIS AND LUMBAR APPENDECTOMY

W WAYNE BABCOCK, M.D., F.A.C.S., Philadelphia, Pennsylvania

A SOMEWHAT rare form of appendicitis which may be mistaken for other conditions unless the symptoms are definitely understood, has not, to my present knowledge been clearly described. It is a type in which the appendix is posterior and lies against the peritoneum dorsal to or below the cecum. The general peritoneal cavity is not involved and the characteristic abdominal symptoms of appendicitis are absent. Without gross perforation and usually without intra abdominal pus formation, bacteria from the appendix penetrate the thin peritoneal layer and spread in the loose extraperitoneal connective tissue of the loin and pelvis, producing first a watery edema like that often seen in the deep tissues of the anterior abdominal wall from appendicitis, but with a much greater tendency to a spreading purulent, and necrotic process. The tela subserosa or extraperitoneal connective tissue of the posterior abdominal wall and pelvis is much more abundant, is looser, contains more fat, and is less resistant to infection than that of the anterior abdominal wall. There results from the lower involvement of the right extraperitoneal space a pelvic abscess, and from the upper type a right perinephritic abscess. Coincidentally inflammatory products within the appendix usually discharge into the cecum and the appendix undergoes resolution.

I have long believed that appendicitis without intra-abdominal suppuration is a common cause of the so-called idiopathic perinephritic abscess. This concept, however apparently has received little attention from urologists, although Hugh Young mentions appendiceal abscess as a possible cause of perinephritic abscess.

If an anterior abdominal incision is made in the early stages of lumbar appendicitis with removal of the appendix, the operator may encounter nothing to direct his attention to

the retroperitoneal inflammation. The peritoneum over the lumbar area is not necrotic or perforated and in the limited area not covered by the cecum, shows no greater inflammatory change than that usually found contiguous to an inflamed appendix. If careful palpation were made a cushion-like elevation of the peritoneum dorsal to the appendix might be detected but I dare say few operators have considered such examination necessary. With the lower type a large extraperitoneal pelvic abscess which later forms may be mistaken for and drained as a localized intraperitoneal collection. Likewise the operator will overlook the primary appendicitis when, without opening the peritoneum, he drains only the secondary retroperitoneal or perinephritic abscess. Apparently the septic extension through the peritoneum is uncommon if the appendicitis leads to a plastic or purulent peritoneal exudate. In other words, the extraperitoneal extension rarely is associated with a gangrenous or perforated appendix.

The signs and symptoms of the lower type of lumbar appendicitis are striking and, when fully developed very characteristic. The attack may start, as in the usual case of appendicitis with epigastric distress, nausea, moderate fever, elevation of the pulse rate, and polymorphonuclear leucocytosis. The pain tenderness, and rigidity however do not localize at McBurney's point but rather in the right lumbar muscles above the crest of the ilium. Medial to the right anterior superior spine of the ilium the signs of appendicitis, such as local tenderness, muscular rigidity and the iliopsoas and obturator tests, may be entirely absent. The patient however may complain of pain and tenderness over the anterior surface of the right thigh, of the right scrotum or in the female of the right labium majus. In the inflamed extraperitoneal connective tissue back of the cecum lie the genitofemoral nerve, the external spermatic branch of which innervates the cremaster and scrotal or labial skin, and the lum-

inguinal branch, supplying the skin of the upper anterior thigh. From involvement of the lateral femoral cutaneous and the femoral and obturator nerves symptoms referred to the lateral surface of the thigh, lower anterior surface or medial surface of the thigh, or knee also, may be produced. As the ureter runs through the intensely inflamed connective tissue, ureteral colic and hematuria may be present. The characteristic syndrome of lumbar appendicitis is lumbar pain tenderness and muscular tension associated with pain in the anterior right thigh, testicle or labium to which may be added vesical irritability and hematuria. A degree of lumbar scoliosis with concavity to the right may develop and later from the inflammatory exudate, the margins of the right psoas muscle may appear blurred or the muscle shadow obliterated on roentgen examination.

The pathological changes can be appreciated only by an incision exposing the extraperitoneal connective tissue in the right lumbar and iliac regions together with the appendix.

In operating an oblique incision is made above the crest of the right ilium along the fibers of the external oblique which are separated and partly divided. The retroperitoneal connective tissue space is entered and evacuated of the inflammatory exudate and wiped dry. The peritoneum is opened by a small incision behind or below the cecum through which the appendix is delivered. The meso-appendix is clamped and divided in sections and the base of the appendix doubly ligated and divided by a cautery between the clamps and beyond the ligatures. The meso-appendix is ligated over the stump of appendix in sections with one of the ligatures. As a rule the opening in the peritoneum may be closed with 36 gauge alloy steel wire and the septic retroperitoneal space drained the wound being closed about the drain with layer sutures of No. 32 wire. The retrocecal appendix lies against the peritoneum and is accessible from the loin.

The following is the report of a typical case of lumbar appendicitis.

Mr H B 22 years of age a medical student became ill in the afternoon with generalized dull

aching abdominal pain after eating Chinese food. At 6 o'clock the following morning he had a severe chill was nauseated and vomited and at 10:00 a.m. he entered the accident dispensary of Temple University Hospital with the diagnosis of a right urinary tract calculus as it was thought that the urine contained blood. At this time the hemoglobin was 13.5 (70 per cent) erythrocytes 5,030,000 color index 80 leucocytes 13,800 polymorphonuclears 83 lymphocytes 13 monocytes 3 eosinophiles 1 nonfilaments 51, filaments 31 urine clear, no sediment, acid, cloud of albumin much amorphous material, blood urea nitrogen 45 milligrams plasma carbon dioxide 0.50. The abdominal ache disappeared and there were several diarrheal movements. (A month previously he had had a transient acute abdominal attack with nausea, vomiting and constipation.)

In the afternoon he was transferred from the accident dispensary to the hospital with the impression that he had an acute gastroduodenitis and possible stone in the right kidney or ureter. His temperature then was 103.3 pulse 86 respiration 22 leucocytes 26,000 polymorphonuclears 89 nonfilaments 78 filaments 11 blood urea nitrogen 60 milligrams, urine 1.018 no casts or blood cells occasional leucocytes.

The patient a well developed and heavily muscled young man was seen in consultation about 4:00 p.m. He then was complaining of pain and sensitiveness in the lower right loin the anterior right thigh and in the right testicle. There was no abdominal distention muscle resistance or tenderness. Posterior to the line of the right anterior iliac spine and above the crest of the right ilium was a painful area with marked tenderness and increased muscular tension. With a diagnosis of retrocecal appendicitis and secondary lumbar phlegmon operation was performed about 4:30 that afternoon.

An oblique 9 centimeter skin incision was made about 2 centimeters above the right iliac crest. The fibers of the external oblique muscle were separated and the lumbar fascia and subperitoneal connective tissue (which were greenish seminecrotic, malodorous, and contained 60 to 90 c.c. of pus) were exposed. The area was mopped out and a 3 centimeter incision made through the peritoneum under the cecum exposing the appendix, which was swollen, injected and very lightly attached to the peritoneum but without perforation or plastic exudate. The peritoneal surface was moist from a very small amount of turbid odorless fluid. The base of the appendix was doubly ligated with No. 32 alloy steel wire, divided by cautery the meso-appendix ligated over the stump with one of the ligatures, and the peritoneal opening closed with fine wire sutures. The wound was lightly united with interrupted wire sutures around a drain extending extraperitoneally from the pelvis.

Pathologic report. The appendix measured 5 by 1 centimeter and was not perforated. The serosa was thickened and injected, the lumen narrowed but not obliterated. The mucosa was infiltrated by plasmato-

cytes lymphocytes, eosinophiles and neutrophiles, the epithelium lacking in many places and the glands replaced by fibrous connective tissue containing inflammatory cells. The picture was that of a healing acute appendicitis with evidence of a previous inflammatory attack. The day following operation the urine contained a few red cells and leucocytes.

The patient had an uninterrupted recovery and was discharged from the hospital 15 days after the operation.

SUMMARY

A type of appendicitis is described in which the inflamed organ has a posterior or retrocecal position, and from which the infection spreads through the thin contiguous peritoneal layer with little abdominal reaction and produces a spreading phlegmon or abscess in the poorly resisting loose areolar tissue of the retroperitoneal space in the right lumbar and pelvic areas. As the signs and symptoms are predominantly in the right lumbar region, I have termed the condition 'lumbar appendicitis'. The appendicitis tends to subside spontaneously probably largely by discharge of inflammatory products through the open lumen of the appendix into the cecum and is associated with so few characteristic symptoms as to be overshadowed in the later development of a perinephritic or pelvic abscess. In those cases in which the appendiceal symptoms are more definite the retroperitoneal extension may be diagnosed and

drained through the abdomen as a localized intraperitoneal collection.

The initial symptoms of lumbar appendicitis usually are abdominal colic, nausea and fever soon followed by pain, tenderness, and muscular rigidity in the loin, but with a degree of fever and possibly a chill unusual in acute appendicitis. This condition is to be attributed to the greater toxic absorption from the retroperitoneal space than from the peritoneum. Especially characteristic are symptoms due to the irritation of structures surrounded by the inflamed extraperitoneal connective tissue, as the right genitofemoral, lateral femoral cutaneous, femoral and obturator nerves and the ureter. The syndrome of pain, tenderness, and rigidity in the lower right loin with pain and tenderness referred to the right testicle and anterior part of the right thigh, occurring after a brief abdominal attack, is quite diagnostic.

In treatment it is important that the appendix be removed and the phlegmon drained through a lumbar or retroperitoneal approach otherwise the surgeon may remove an inflamed appendix and overlook the retroperitoneal phlegmon, or drain the pelvic or perirenal abscess and overlook the appendix. With removal of the appendix the peritoneum may be closed, or drained with the lumbar pelvic space through a single lumbar incision.

CORRECTION OF BLOOD LOSS DURING SURGICAL OPERATIONS

CLARENCE E. CROOK, M.D. VIVIAN IOB Ph.D. FREDERICK A. COLLIER M.D. F.A.C.S.
Ann Arbor Michigan

THE study of blood changes produced by hemorrhage has received much attention in the past. Considerably less is known about the changes produced in the circulating blood by various types of anesthesia, the intravenous injection of fluids and the various exigencies of major surgical operations. These variables are so numerous that systemic consequences of traumatizing operations are not reflected in the circulating blood and the determinations of hematocrit, hemoglobin or plasma proteins give little information as to the quantity of blood lost or of pending shock. Support for this statement is found in a brief review of the literature and in the analysis of the blood changes of 35 patients undergoing major surgical operations to be presented.

Dyson, Plaut, and Vaughan observed the reactions to changes in the blood volume resulting from the removal of 540 milliliters of blood from 8 healthy donors in whom many of the variables were reduced to a minimum. They noted that in only one instance the change in blood volume as determined by the dye method was found to correspond to the calculated value. In the others dilution or overdilution was associated with an increase in mean corpuscular volume suggesting that some of the fluid replacing the blood lost was absorbed by the red cells. The authors also point out that blood loss may occur without affecting the hemoglobin level.

A rarely considered variable in the normal individual undergoing blood loss is the uncertain amount of blood expressed from the spleen. According to Lewis, Werle, and Wiggers, the spleen contracts vigorously during hemorrhage, and may shrink to a volume of 50 per cent or less of its original size. Wu in

1943 found the capacity of 20 spleens to vary from 60 to 400 milliliters, a volume which may be added to the blood volume during hemorrhage.

Thus it is evident that, even in simple uncomplicated hemorrhage in relatively normal individuals variable factors contribute to make changes in hemoglobin, plasma proteins, and hematocrit unpredictable. To these factors must be added the inherent differences present in each surgically sick patient and the various methods used in treatment. In general, surgical operations, anesthesia, shock, varying degrees of dehydration and malnutrition, fever, anemia, hypoproteinemia, and intravenous infusions of crystalloids, plasma and variable whole blood all contribute to changes in the circulating blood.

Windfeld, in 1937 made direct measurements of blood lost during operations and demonstrated that determinations of hemoglobin concentrations before and after operation failed to give quantitative information regarding the amount of blood lost.

Stewart and Rourke, recording the changes in the volumes of blood and interstitial fluid during operations under ether anesthesia, stressed the fallacy of assuming a quantitative relationship between changes in concentration of hemoglobin or plasma proteins and changes in plasma volume. From their observations reduction in plasma volume may be greater than can be accounted for by hemorrhage.

Ariel, Pack, and Rhoads compared liver biopsy specimens secured at the beginning and the end of gastric operations and found that hepatic cells usually swell during surgery. The average increase in total liver water was 11 per cent. By inference, the red blood cells also may take up some of the fluid transferred from the interstitial space to the blood stream.

In March 1945 Evans published conclusions resulting from the recent studies of three

Assisted by Grant from the Horace H. Rackham Fund.

†Trifluoroacetic acid, nitrous oxide, local anesthetic

separate shock research groups (of New York, of Atlanta, and of Richmond) in which estimations of blood volume were made by means of the dye method. He presented simple reasons why the determination of hemoglobin and plasma proteins does not suffice in estimating the blood volume in surgical patients. He pointed out that "in whole blood loss almost equal quantities of red cells and of plasma are missing so that hemoglobin and plasma protein concentrations will be relatively unchanged and the surgeon is given a false sense of security. In situations when moderate quantities of red blood cells and much plasma are lost, there will be hemoconcentration yet there is no indication of red cell loss. Only in situations of relatively simple plasma loss (such as peritonitis and some burns) will hemoglobin and hematocrit give an accurate picture of the trend of blood volume alterations."

Introduction of intravenous fluids further complicates the picture. Although Bogert, Underhill, and Mendel found, in 1916 that the blood volume of rabbits injected intravenously with saline returned to normal 30 minutes after the injection later investigations have shown that alterations in blood volume following intravenous infusions last

much longer. Gilligan, Altschule, and Volk found that the blood volume increases after intravenous fluids may not return to the normal level for 2 hours.

The blood at the end of operation is thus the resultant of these variable influences, and it becomes impossible to select any one chemical determination indicative of the condition of the postoperative patient, unless it is the determination of the plasma volume, a laborious and often unsatisfactory procedure in the seriously ill patient.

In support of this statement, the data compiled from the determinations of hematocrit, hemoglobin and plasma proteins of 35 patients before and after major surgical operations are presented in Tables I through VI. In each instance the preoperative value is recorded and below it the percentile change from the preoperative value obtained at the end of operation. The blood lost at operation was determined and has been reported elsewhere (4). Heparinized blood was used, and a 2 milliliter sample sufficed for the 3 determinations. Hematocrit was measured in sealed, capillary tubes spun until no further change in cell volume occurred. Hemoglobin was analyzed as oxyhemoglobin by the photoelectric method of Evelyn on 20 cubic mill-

meters of well mixed blood measured in the falling drop pipet with the aid of a Guthrie pipet holder. This procedure was adopted to avoid the inaccuracies of the 20 cubic millimeter blood pipet. Plasma proteins were determined by the method of Barbour and Hamilton and by the use of Weech's formula. Hemolyzed plasmas were corrected for hemoglobin by an adaptation of Evelyn's method before the plasma proteins were calculated from the plasma specific gravity.

Table I is concerned with the changes occurring during thyroidectomies. In this group only 1 patient received no intravenous fluid. This patient (3) lost 227 milliliters of blood or 7.5 per cent of his total blood volume.¹ A comparison of the percentile changes of both hematocrit and hemoglobin (-10.1 per cent and -10.3 per cent, respectively) and the calculated blood loss (7.5 per cent) indicates an overdilution, similar to the reaction of healthy donors to the withdrawal of blood.¹

All the other patients in Table I received 5 per cent glucose intravenously during the operation. Patient 10 with a blood loss of 204 milliliters or 5.3 per cent showed little or no tendency to hemodilution above that of the blood lost, in spite of 1000 milliliters of glucose infused during the operation. In other words, approximately 750 milliliters of fluid have left the blood stream during the operation.

¹Total blood volume was calculated from the average values determined by Osborn and Evans, 77.7 milliliters per kilogram of body weight in the male and 60 milliliters per kilogram in the female.

In contrast, patient 15 showed changes in hematocrit (-5.9 per cent) comparable to the blood loss (-6.0 per cent) but both hemoglobin and plasma proteins remained unchanged. This instance suggests an absence of hemodilution and even a shrinkage of the red cells.

Patient 16 was operated on for a very large toxic goiter. In spite of the large blood loss of 725 milliliters, 28 per cent of the total blood volume and the infusion of 1000 milliliters of glucose there was no evidence of hemodilution. Later patient 16b during the second stage of the hemithyroidectomy showed a similar reaction. These findings suggest the rapid disappearance of the intravenous fluid and the absence of hemodilution after large losses of blood.

Table II presents the results of studies during radical mastectomies. Patient 1 received 1000 milliliters of glucose during the operation which involved a blood loss of 821 milliliters or 12.8 per cent of the total blood volume. She developed mild hypotension. The percentile change in hemoglobin (-15.3 per cent) corresponded to the blood loss (-12.8 per cent). The hematocrit change (-2.3 per cent) is rather indicative of increase in mean corpuscular volume.

In patient 29 with a loss of 14.6 per cent of the total blood volume, the change in hemoglobin (-18.9 per cent) and in plasma proteins (-17.3 per cent) corresponds to the blood loss with a tendency toward overdilution while

the hematocrit (-11.1 per cent) is indicative of cellular swelling.

In these mastectomies the changes in hemoglobin compared more closely with the blood loss than did the changes in hematocrit or plasma proteins. However even the hemoglobin changes are often misleading. Blood losses were large averaging 800 milliliters and hypotension occurred frequently.

Patients undergoing combined abdominoperineal resection for carcinoma of the rectum are represented in Table III. Here the average changes in hematocrit (-5.1 per cent) hemoglobin (-8.0 per cent) and plasma proteins (-6.6 per cent) correspond fairly well with average blood loss (-3.2 per cent) but suggest a tendency toward overdilution. Individually this ideal correlation exists in only one instance, patient 30. The other cases show considerable variation. For example patient 7 sustained a blood loss of 183 milliliters (4.1 per

cent) of the total blood volume. This patient's reaction to the small loss of blood was a change in hematocrit of +10.7 per cent, in hemoglobin of -17.6 per cent and in plasma proteins of -1.1 per cent. A fairly pronounced hypotension may have been responsible for some of these shifts.

Difficult and prolonged surgery for diseases of the biliary tract provided the cases in Table IV. In these patients hypotension is frequently a prominent part of the surgical picture. In spite of the existing marked hypotension patient 18 presents blood changes comparable to the hemodilution resulting from a blood loss of 8.1 per cent. On the other hand patient 21 after a corrected blood loss of 14.4 per cent (total loss less transfusion during operation) showed a hematocrit change of -4.5 per cent, a hemoglobin change of +1.5 per cent, and a plasma protein change of -11.1 per cent.

4. Biliary tract	8	504	-14.6	-8	+1.5	-4.8	-4
5. Gastric lesions	2	529	-13.8	-6	+7	+	+7.6

*After replacement of blood during the operation.

As mentioned before Pack and associates (1) demonstrated swelling of liver cells in patients following operation on the stomach. The cases presented in Table V show evidence of swelling of red blood cells as shown by the increased hematocrit.

Table VI summarizes the average blood losses and the average changes in hematocrit, hemoglobin and plasma proteins. Blood losses calculated from the changes in hematocrit, hemoglobin, or plasma proteins would lead to an underestimation of the need for replacement in mastectomies thyroidectomies, biliary tract surgery and gastric lesions. In combined abdominoperineal resections, the individual estimates would also be uncertain in spite of the fact that the average values shown in the series correspond fairly well to the blood lost.

COMMENT

Thus, an analysis of the findings in the 35 cases here presented furnishes further evidence that no easy practicable laboratory procedure will indicate the status of the circulating blood in the postoperative patient.

Studies of blood loss invariably show that the loss is almost always greater than the surgeon estimates. It is becoming widely recognized that the only wholly suitable replacement for operative blood loss is whole blood and that the greatest benefits result when the blood is given as the loss occurs.

The surgeon therefore, should plan in advance for the adequate replacement of the deficiency caused by bleeding during the operation. To do this, he must usually rely upon his own knowledge of the amount of blood loss to be expected in each case. Recognizing this fact the present authors, in a previous publi-

cation (4) tabulated the average blood losses occurring during the usual types of operations as calculated from 626 cases reported in the literature.

CONCLUSIONS

Whole blood is required adequately to replace blood lost during surgical operations. The replacement is most effective when whole blood is given as the loss occurs.

The amount of blood needed in each surgical case can seldom be determined directly. Hemoglobin, hematocrit, and plasma protein concentrations fail as an accurate measure of this need. Plasma volume determinations are more accurate, but are too laborious and time consuming for routine use.

A knowledge of blood loss during operation as available in the literature offers a practical basis for planned transfusions during operation.

PATELLECTOMY IN THE MILITARY SERVICE

A Report of 19 Cases

THOMAS HORWITZ, M.D. F.A.C.S. Lieutenant Colonel M.C. A.U.S. Philadelphia
Pennsylvania, and R. G. LAMBERT Captain M.C. A.U.S. San Francisco California

THE subject of patellectomy or complete excision of the patella has long been a controversial one. Those opposing the procedure argue that if the patient regains complete flexion of the knee there is resulting limitation of extension and conversely if he has complete extension he cannot fully flex the knee (Fig 1a b).

We believe that patellectomy can be a very successful operation and that patients with complete patellectomy can have normal knee function. Many operations have been devised for this procedure each claiming some special advantage. We carry no banner for any particular operation, but believe only that the essential aim should be to eliminate the slack in the quadriceps tendon which is created when the patella is removed.

The amount of slack to be eliminated has not been adequately defined in the literature. Consequently we have herein attempted to clarify the subject on a mathematical basis, although realizing that the figures used are averages and do not apply to any given case. For purposes of the computations we have accepted 2 centimeters as the average thick-

ness and 5 centimeters as the average length of the patella, and we have further assumed that the quadriceps tendon drops the entire 2 centimeters when the patella is removed (which is not entirely true in view of the thickness of the quadriceps tendon itself). We have computed that this portion of the quadriceps tendon becomes lengthened to about 6.4 centimeters or a gain of about 1.4 centimeters.

Since muscle power is directly related to the length of the individual fibers and hence to overall contractile length it can be readily seen that a gain in length of $1\frac{1}{2}$ centimeters would be disastrous to function both in strength of the quadriceps and in range of extension of the knee. This point has not been adequately clarified and for this reason we insist that the elimination of the slack is the important principle in the operation and that it makes little difference whether the patella is reached through a transverse parapatellar or other approach.

The operation we have used is as follows (Fig 2). The patella is approached through a short median parapatellar incision. A straight longitudinal incision is made through the quadriceps expansion in the midline of the

Presented at the meeting of the Chicago Orthopedic Society April 3, 1945, at V. Nathan General Hospital, Hines, Illinois.

Fig 1. Patient A.L., aged 24 years. Chondromalacia patellae of right knee. a and b, Photographs made 8 weeks

after operation demonstrate restoration of full range of extension and flexion.

Fig. 2. Incisions and method of lateral plication. 1, Median parapatellar skin incision. 2, Longitudinal incision of quadriceps tendon in middle of patella. Patella partially exposed with beginning undermining of tendon anteriorly. 3 and 4, Patella exposed. Lateral plication performed with knee in full extension, by use of No. 00 black silk mattress sutures.

Fig. 3. (a) The arc is assumed to equal its chord. Application of Pythagorean theorem shows chord to equal the square root of 0.25 or 0.5 , and the length of the quadriceps tendon then is 6.4 centimeters, or 0.4 centimeters longer than the patella. (b) The same assumptions apply; the chord in this case being 0.3 and the width of the quadriceps tendon then is 5.6 centimeters or 0.6 centimeters wider than the patella. It is to be noted that the figure for longitudinal slack— 4 centimeters—bears no relation to the figure for lateral plication, 1.6 centimeters.

patella, extending 1 centimeter above and below the limits of the bone. The expansion is then removed by sharp dissection left as intact as possible and the patella is removed after cutting through the synovial attachments. The quadriceps tendon is then plicated laterally a distance of 1.6 centimeters at the midpoint and tapering toward both ends. This figure is arrived at as before by assuming the thickness of the patella as 2 centimeters, the width as 4 centimeters, and the slack to be eliminated being computed as 1.6 centimeters (Fig. 3). In actual practice if one merely plicates all the available tissue in the lateral direction without tension the result will be the same. However this plica-

tion must be performed with the knee in full extension since in flexion the slack will be loosened and the computations made become invalid. The plication is done with No. 00 silk, reinforced with single sutures. The subcutaneous tissue and skin are closed as usual.

Postoperatively the patient is immobilized in balanced suspension with the knee in full extension for 1 week and is then started on active exercises. Quadriceps setting is begun in 24 hours. Patients can usually begin weight bearing within 2 weeks.

The conditions for which patellectomy is most often indicated are recent comminuted

fractures, old fractures with roughening of the articular surface of the patella or femoral condyles, chondromalacia patellae and dislocations, habitual or recurrent of traumatic paralytic, or congenital origin. In addition removal of the patella may be indicated in the treatment of degenerative arthritis, local septic lesions and tumors of the patella.

CLINICAL MATERIAL

Nineteen total patellectomies are now available for study data are presented in Table I.

In patients with chondromalacia patellae as the underlying pathological process there

has been a normal range of motion preoperatively but with associated knee joint symptoms. Postoperatively in all cases, there has been a rapid recovery of normal motion with a subsidence of all symptoms.

In those cases in which there has been limitation of joint motion preoperatively as in the compound fractures there has been a definite improvement in the range of motion although normal motion has not been attained. We believe that in these cases failure of return of normal motion is due to associated intra articular damage found in all cases on the roentgenograms and at the time of surgery. In this respect it is noteworthy that there was normal motion preceding and following patellectomy in patient M J with a comminuted fracture of the patella due to a perforating bullet wound in whom there was no demonstrable associated joint damage. All patients have been relieved of their knee joint symptoms and excellent function has resulted in spite of the limitation of motion.

We have concluded that whereas in all cases the patient is alleviated of his knee joint symptoms and has shown an improvement in or normal restoration of motion *this postoperative return of joint motion has been*

conditioned by the range of motion existing prior to surgery

CONCLUSIONS

1 While we hold no brief as to the incision used for removal of the patella, we believe that the median parapatellar skin incision and the longitudinal incision of the tendon are best adapted to the method of lateral plication.

2 The slack to be eliminated by the method of lateral plication has been computed to be 1.6 centimeters with the knee in full extension.

3 In this series of 19 patellectomies, (10 compound comminuted fractures, 8 cases of chondromalacia and 1 ununited simple fracture) all patients have been relieved of knee joint symptoms.

Whereas all patients have shown improvement in or normal restoration of function, postoperative return of function has been conditioned by the range of motion existing prior to surgery. Those patients who have had a normal range of motion before surgery will regain a normal range of motion following removal of the patella. Those patients with limited motion preoperatively due to associated joint damage have shown a measurable improvement in range of motion.

BRONCHOPNEUMONIA FOLLOWING ETHER ANESTHESIA IN OBSTETRICS

HOMER C. HARTZELL, M.D., and EDWARD P. MININGER, M.D. Cleveland, Ohio

A SERIES of cases of bronchopneumonia has been observed in patients on the obstetrical service at Cleveland City Hospital. These bronchopneumonias observed within a few days following delivery were variable in extent, transient in nature, and were not associated with clinical evidence of serious illness. They were discovered in almost all cases by means of a roentgenogram of the chest made to investigate the significance of slight fever or rales in the chest developing after delivery. The anesthesia in these cases consisted of ether administered usually by the open method and preceded by varying quantities of barbiturate and other premedication. The mechanism by which the pneumonias were produced was probably the aspiration of mucus or vomitus during or following anesthesia. Other factors which may be considered are suppression of cough reflex and retention of secretions due to the irritation of ether.

Further study of these cases was undertaken because of the frequency with which they were observed and because some of them were incorrectly diagnosed.

REVIEW OF LITERATURE

A search of the literature revealed that little attention has been paid to aspiration pneumonia as a complication of anesthesia in obstetrics. Hall in 1940 called attention to aspiration pneumonitis as an obstetric hazard by reporting 15 cases of aspiration pneumonia following delivery. His cases were of a serious nature, since 5 died and several others required prolonged hospitalization. He commented that the aspiration of solid material into the trachea or bronchial tree might produce death from respiratory obstruction, while the aspiration of fluid material produced some

sort of chemical pneumonitis. He discussed a number of factors including diet prior to delivery, position of the patient during anesthesia, and premedication which he thought might be related to the problem of aspiration of gastric contents. Autopsies were obtained in 2 of his 5 fatal cases. One showed both lungs full of a diffuse wet consolidation with air present only at the extreme apexes. The second was found to have both lungs collapsed and the bronchi of each lung filled with dark colored contents, apparently spinach or some other dark food.

Meurlin in 1941 reported a series of 7 deaths occurring in Essex County, New Jersey, in a period of 4 years, developing during or soon after labor and directly caused by the aspiration of stomach contents. He stated that in addition to these 7 cases, many other deaths had occurred which were probably also of this nature, but which were not included in his report due to lack of accuracy of the available information or because of their controversial nature.

SUMMARIES OF TYPICAL CASES

CASE 1. V. M., a white woman 25 years of age, was admitted to the tuberculosis division of City Hospital on August 26, 1934. Four days prior to her admission, following a labor of 15 hours' duration, she was delivered of a healthy infant at a maternity hospital elsewhere in the city. Ether anesthesia was administered for 40 minutes, preceded by seconal medication and was followed by vomiting. Evidence of bronchopneumonia appeared and on the day following delivery she was transferred to a general hospital. At this hospital a roentgenogram of the chest made 2 days following admission showed irregular mottled and feathery shadows of increased density distributed symmetrically throughout all of both lung fields. Since the radiologist interpreted these changes as due to pulmonary tuberculosis, the patient was transferred to the tuberculosis division of City Hospital. On admission she was afebrile, did not appear ill, but presented scattered inspiratory musical rales bilaterally. The admission roentgenogram of the chest, made 6 days following delivery again showed diffuse bilateral mottled infil-

Fig. 2 Case 2. Extensive patchy symmetrical bilateral bronchopneumonia.

tration less extensive than that observed on the submitted roentgenogram. Because of the symmetry of her pulmonary disease, the healthy appearance of the patient, and the absence of pulmonary symptoms, pulmonary sarcoidosis was suspected. Another roentgenogram of the chest made 10 days following admission showed the pulmonary infiltration to have undergone complete resolution. Since the rapidity of clearing of the infiltration excluded both pulmonary tuberculosis and sarcoidosis, it was evi-

Fig. 5 Case 5. Dense coalescent infiltration involving lower two-thirds of right lung field, and left hilum.

dent that the process represented a widespread bronchopneumonia. The patient was discharged on September 16, 1944, to the care of a private physician.

CASE 3. F. N., a colored woman 22 years of age, was admitted to the obstetrical service on March 15, 1944, in active labor. Secoval was administered in a dose totalling 3 grains as premedication. Delivery was effected following a labor of $3\frac{1}{2}$ hours' duration. Ether anesthesia was employed. Vomiting of particulate and fluid gastric contents occurred during and immediately following anesthesia. Dyspnea and cyanosis developed. Bronchoscopic aspiration was immediately performed with relief of dyspnea, followed by the administration of sulfathiazole for a period of 3 days. The temperature rose to 38.5 degrees Centigrade for a period of 1 day after which it remained normal. Scattered rales were present throughout the chest. The total white count on the day following delivery was 12,800 white cells per cubic millimeter. A roentgenogram of the chest made 1 day following delivery showed the presence of coalescent, poorly demarcated shadows of increased density distributed symmetrically throughout both lung fields, interpreted as bronchopneumonia. Following the initial episode of obstructive dyspnea, the patient did not show evidence of serious illness. A second chest radiograph made 8 days following delivery showed complete resolution of the bronchopneumonia. She was discharged April 3, 1944, 11 days following her hospital admission.

CASE 5. D. T., a white woman 27 years of age, was admitted to the delivery room on March 11, 1944. Delivery was effected following a labor of 17 hours' duration. Inhalation gas oxygen ether anesthesia was used, preceded by morphine and scopolamine medication. The anesthesia was complicated by

vomiting. A roentgenogram of the chest made 3 days following delivery showed the presence of mottled and conglomerate shadows of increased density involving the lower two-thirds of the right lung field and the left hilum area interpreted as bronchopneumonia. Despite the extent of the infiltration as observed roentgenologically the patient did not appear ill and her temperature did not exceed 38.2 degrees Centigrade. An x ray film of the chest made 4 days later showed the bronchopneumonia to have undergone complete resolution. She was discharged in good condition on April 4, 1941.

CASE 4 E S a colored woman 19 years of age was admitted to the delivery room on February 12, 1945. Delivery was effected under ether anesthesia preceded by atropine. The patient vomited shortly following delivery. Twelve hours later she developed

Fig. 4. Case 5. Dense infiltration situated in the right upper lobe.

a shaking chill and her temperature rose to 38.8 degrees Centigrade. A roentgenogram of the chest made on the day of delivery showed mottled shadows of increased density in the lower and medial portion of the right lung field and in the left hilum area interpreted as bronchopneumonia. Sulfadiazine therapy was begun. The patient remained febrile for only 1 day and recovered uneventfully. Another roentgenogram of the chest made 6 days following admission showed the pulmonary infiltration to have undergone complete resolution. She was discharged 8 days following admission.

CASE 5 B J a white woman 19 years of age was admitted to the obstetrical service on November 9, 1943. She was delivered under ether anesthesia preceded by morphine and scopolamine medication following a labor of 15 hours duration. After delivery she developed fever rising to a maximum of 38.4 degrees Centigrade. A roentgenogram of the chest made 1 day following delivery showed a dense mottled infiltration in the upper lobe of the right lung interpreted as pulmonary tuberculosis. Although she did not present clinical evidence of serious illness she was treated with sulfathiazole for a period of 3 days. A second chest roentgenogram made 9 days following delivery showed the infiltration to have undergone complete resolution indicating that the original diagnosis of pulmonary tuberculosis was erroneous. She was discharged in good condition on November 21, 1943.

EVALUATION OF STUDY

Information concerning the 20 cases comprising this series is included in the accompanying tabular summary.

of the vessel markings has been found suggestive of pulmonary hyperemia. None of the patients have shown mediastinal displacement or other evidence of massive atelectasis.

Clearing of the infiltration was rapid in most cases and complete in all. Fifteen of 18 cases in which serial films are available showed complete clearing in 1 week or less. The time of clearing in the other 3 cases is not known with certainty but complete disappearance of the infiltration was demonstrated on the eighth, ninth, and twenty first days, respectively.

On strictly objective criteria, a roentgenologic diagnosis of aspiration pneumonia is not possible, but its recognition is usually easy if the roentgenologist has the clinical findings available to him, and if he is familiar with the condition. It may be confused chiefly with pulmonary tuberculosis, sarcoidosis, atelectasis, pulmonary edema, and other pneumonias. It is differentiated from both pulmonary tuberculosis and sarcoidosis by its rapidity of clearing as seen on serial films. It differs from lobar or massive atelectasis in its patchy character and in the absence of mediastinal displacement. Dependence must be placed upon the clinical findings to differentiate it from bronchopneumonias and pulmonary edemas of other etiology.

It is evident that a roentgenogram of the chest made shortly following delivery may be a confusing diagnostic measure if its purpose is the detection of early pulmonary tuberculosis. Chest roentgenograms made for this purpose should be taken either prior to delivery or 2 weeks or more following delivery.

CLINICAL ASPECTS

The immediate sequel to vomiting during anesthesia has been respiratory distress. In 1 of the cases, this distress was sufficiently serious to require bronchoscopic aspiration for relief. In the remainder more simple measures proved adequate. There were no fatalities in this series, although the possibility of an immediately fatal issue is indicated by the reports of Hall and of McEurlin.

The height of the fever manifested in these cases is indicated in the accompanying tabular summary. It was unusual for fever to be sus-

tained at a high level most of the patients presented one or several spikes of fever with prompt fall either to normal or to a level below 38 degrees Centigrade. None presented the appearance of septic illness, and in none were clear-cut localized physical signs of consolidation, other than rales, discovered. A slight leucocytosis, averaging 10,000 to 12,000 white cells per cubic millimeter was present in some.

PATHOGENESIS

Two chief questions arise concerning the origin and nature of these bronchopneumonias, namely what is the nature of the pathologic change in the lungs, and what is the explanation for the benign clinical course observed in these patients?

It is generally recognized that, in addition to the classical forms of massive atelectasis, smaller areas of lobular or patchy atelectasis may occur as the result of occlusion of finer bronchiolar radicles. It is probable that the shadows seen in the roentgenogram are in part due to such patches. Another factor contributing to the pulmonary changes is the reaction of the lung tissues to the irritant gastric contents, namely hyperemia, hemorrhage, edema, and exudation. Finally areas of bacterial pneumonia may occasionally supervene in areas in which virulent organisms have been implanted.

The failure of the cough reflex to expel the foreign material from the bronchial tree is probably in part due to the massiveness of the aspiration, and in part to the fluidity of the aspirated material. Archibald and Brown have shown that cough, instead of expelling material from the bronchial tree, may actually cause it to be driven deeper into its ramifications. In their experiments upon animals, iodized oil was disseminated in the bronchial tree by cough, while thick tenacious sputum, being a heavier substance, was expelled. The dissemination of iodized oil by cough is a matter of common observation in bronchography. On the basis of the experiments of Archibald and Brown, it is probable that gastric contents, because of their fluid nature and slight viscosity are widely disseminated in the bronchial tree by cough, and inefficiently and incompletely expelled.

The benign course of these bronchopneumonias has been noteworthy. One factor responsible is their incidence in a group of young healthy women without evidence of cardiac or pulmonary disease. A more important factor is the probable presence in these patients because of their age of an adequate gastric acidity, inhibiting the growth of pathogenic bacteria.

Other than coincidence (suggested by the reported deaths in other series) the only factors known to have prevented immediate death from asphyxiation have been postural drainage of the bronchial tree, and its aspiration by catheter suction in 1 instance bronchoscopically for relief of respiratory distress.

FACTORS PECULIAR TO OBSTETRICAL ANESTHESIA

A number of factors may play a part in the frequency of aspiration pneumonia in obstetrical cases. First is the frequent necessity for administering an anesthetic when the patient's stomach is laden with food. Second is the possible effect of premedication by barbiturate or by morphine in depressing protective reflexes or inducing vomiting. Third the depth of anesthesia demanded in good obstetrics is dangerously near the level at which vomiting may readily occur even when expertly administered. Daily observation suggests that the time of gastric evacuation is prolonged in labor and Meurlin states that 'a delayed emptying time of the stomach during labor is a factor which should be kept in mind.' Finally vomiting is occasionally seen in the latter part of the first stage of labor and during the portion of the second stage of labor preceding anesthesia. This may occur independently of medication and is probably of reflex origin.

PREVENTION AND TREATMENT

The well known measures of postural drainage of the bronchial tree and its aspiration by catheter suction or bronchoscopically are the recognized methods of treating vomiting and aspiration during anesthesia.

The aspiration pneumonias in this series have not been of sufficient clinical severity to require the use of chemotherapy nor did

chemotherapy affect the course of those patients in which it was used.

The administration of an emetic in early labor to the woman who has recently eaten solid food has been practiced in this community. Gastric evacuation by induced emesis, when carefully executed, might prevent the postanesthesia vomiting and aspiration of particulate matter.

The properly trained anesthetist will be able in most instances to maintain his patient in the narrow zone of anesthesia in which the labor processes are allowed to continue without the development of vomiting.

SUMMARY AND CONCLUSIONS

1 A series of 20 cases of bronchopneumonia was observed at Cleveland City Hospital which developed following obstetrical delivery in which ether inhalation anesthesia was used.

2 Their chief cause was the aspiration of gastric contents as a result of vomiting. The possible contributory rôle of the following factors was discussed: (1) preanesthetic medication favoring suppression of the cough reflex, (2) prolonged gastric evacuation in labor, (3) fluidity of gastric contents favoring their dissemination in the bronchial tree.

3 The bronchopneumonias varied in extent from small isolated patches to extensive bilateral infiltrations. They were observed in all portions of the lung fields.

4 Clinically they did not prove a cause of serious illness and no fatalities resulted. Chemotherapy by sulfonamide drugs was apparently not effective.

5 Roentgenologically the problem was one of differential diagnosis, requiring differentiation from pulmonary tuberculosis, sarcoidosis, other pneumonias, pulmonary edema and atelectasis.

THE RETROGRADE LYMPHATIC SPREAD OF CARCINOMA OF THE "RECTOSIGMOID REGION"

Its Influence on Surgical Procedures

ROBERT P. GLOVER, M.D. and JOHN M. WAUGH, M.D., F.A.C.S., Rochester, Minnesota

FEW organs of the body have been subjected to more intensive and exhaustive study in recent years than has the rectum. This is particularly true with reference to carcinoma and its potentialities in this region. Needless to say we are still far removed from an understanding either of its cause or of its specific cure although admittedly great strides have been made especially with regard to its surgical treatment. Those advances that have been made are based on a more thorough understanding of the nature of cancer of the rectum including the form which it is likely to assume its rapidity of growth, its mode of spread and its final outcome. Here as elsewhere it has been learned that malignant disease with perhaps some few exceptions, can be adequately controlled only by complete extirpation hence the innumerable surgical methods and modifications that have come into practice.

Moynihan in 1908 made the significant statement that the surgery of malignant disease is not the surgery of organs it is the anatomy of the lymphatic system. Nowhere is this more applicable than to malignant disease of the rectum. It is toward the anatomy of the lymphatic system that the greater portion of this study has been directed. Many investigators in the past and present have devoted much of their time to its study and the results of their work as well as the conclusions of this research will be correlated in an attempt to determine what an adequate method of treatment for carcinoma of the rectum and particularly of the rectosigmoid region implies.

If as has been the dream of surgeons for many years, cancer of the rectosigmoid and upper part of the rectum with its involved diseased region can be removed, with restoration of normal continuity to the bowel and preservation of sphincteric control, a great contribution will have been made. It was with such an aim in view that this study was undertaken for should it be feasible from a pathologic standpoint an impetus for refinements in surgical attack and technique will surely follow. As carcinoma of the rectum represents some 4 per cent of all cancers (1-15) it is evident that the number of patients who might be concerned is considerable and any pathologically sound attempt to avoid the construction of an artificial anus will be well repaid. Such attempts have been numerous and with good result when properly carried out but have been frowned on by many who believe them to be more sensational than radical, basing their belief primarily on the work of Miles.

SPREAD OF CARCINOMA

Malignant disease may spread primarily in one of three ways by local extension from its site of origin by invasion of venous channels and through the lymphatic system. An evaluation of any therapeutic approach to carcinoma in a given region must therefore take into its scope each of these avenues. Although an extensive literature concerning the first two of these modes of spread exists, the original work of this paper deals only with certain aspects of lymphatic spread and consequently discussion other than of the lymphatics must necessarily be limited to a few short statements.

Local extension. Carcinomas of the rectosigmoid are relatively slow-growing malignant lesions. Microscopically three quarters of

Abridgment of thesis submitted in September, 1944, by Dr. Glover and accepted in November, 1944, by the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of M.S. in Surgery.

them are of low grade, so that one would expect considerable local growth before any widespread metastasis has occurred. W J Mayo (25) emphasized this point in 1910 and reiterated it repeatedly (26 27) as have other writers (4 33). Indeed, in his experience local extension more than any other factor, including lymphatic and hepatic involvement, was the common cause of inoperability. That distant metastasis may occur while the mass of the disease remains localized is of course well recognized and indisputable but by and large it may be stated that a considerable period elapses in most cases before this occurs. It is obvious therefore, that all locally involved tissues must be removed at the time of operation and to accomplish this end it is absolutely essential that wide excision through healthy tissues be practiced.

Venous spread Once carcinoma has spread into venous channels with the formation of malignant thrombi and dispersion of malignant emboli, no surgical procedure however radical can be devised to rid the patient of his affliction. Were such a sequence of events customary the prognosis for cancer of the rectum would indeed be grave. Fortunately this does not obtain although investigations within the last decade tend to show that it is a more frequent occurrence than was formerly suspected.

Intravascular invasion seems remarkably constant, occurring in approximately a fifth of all cases of malignant lesion of the lower part of the colon (8 13 34). As would be expected, the higher the grade of malignancy the higher becomes the incidence of venous involvement and the greater the probability of visceral metastasis (3).

Perhaps the most significant observation concerning venous spread was made by Clogg in 1904. He noted that when dissemination via the blood stream occurred it frequently did so before the disease had spread to lymph nodes. Recent studies (13) have confirmed this impression and enlarged on it to show that most vascular invasion originates within the involved intestinal wall itself or within the immediately adjacent perirectal tissues and not from more distant extensions. Consequently although sharply limited and seem-

ingly favorable for surgical removal, a rather innocuous-appearing cancer may prove as deadly as the most widespread and perforating types. Such cases explain why the rate of cure declines in direct proportion to the degree of penetration even though no involvement of perirectal fat or lymphatic network be found. It must be obvious therefore that the threat of venous spread demands early rather than radical surgical intervention the latter being directed more especially against local and lymphatic expansion.

Lymphatic spread As carcinoma spreads through the ramifications of the lymphatics in a most systematic and relentless manner, the problem of its control must be met with equal thoroughness and determination. To do so entails an intimate knowledge of all pathways over which such an advance may occur. The literature contains several detailed and exact studies (9 32 35) to which reference may be made with considerable profit and from them Figure 1 has been constructed.

Anatomic review Considering the anus and rectum as one continuous tube it may be divided into three regions corresponding roughly to the areas supplied by the inferior, middle and superior hemorrhoidal arteries. The inferior region is the 2.5 centimeters of anus proper terminating superiorly at the pectinate line. The middle region extends upward from the pectinate line to a point just above the insertions of the levator ani muscle. The superior region extends from this point to the sigmoid colon and terminates approximately at the level of the third sacral vertebra. This latter is the largest of the three regions.

The lymphatics in all of these regions originate in a rich network of tiny lymph spaces the extremely close meshes of which extend throughout the mucosal, submucosal and intermuscular layers. Although continuous diversified connections of this network have been said to exist between all three regions for the most part they may be found to unite into their own collecting trunks, which further join to terminate in lymph nodes after the full thickness of the intestinal wall has been traversed. Thus the direction of flow is essentially at right angles to the long axis of the bowel,

Fig. The extramural and intramural lymphatic systems of the rectum (intramural system after Letch)

even though many small intermediary branches may course in any direction en route to their final destination. In other words lymph potentially able to spread from anus to sigmoid in whole or part via these small channels never does so a point which will be discussed in some detail presently under intramural spread. Having thus arrived in the collecting trunks drainage proceeds according to definite pattern.

1 Inferior and middle regions. Although drainage from the inferior and middle regions is not strictly a concern of this work, it may be pointed out in passing that most if not all of the lymph originating in the region at the same level as, or immediately above, the insertions of the levator ani flows upward, joining the pathways of the superior region. Some may however spread laterally along the levator muscles, either superior or inferior to them and some may also spread caudally through the adipose tissue of the ischioanal fossa. Thus the lymphatic pattern of the middle region might possibly in certain instances be designated as being 'perineopelviabdominal' (Fig 1)

2 Superior region. Numerous efferent trunks pass through the muscular coat at

different levels. Most frequently these trunks become satellites of the branches of the superior hemorrhoidal vessels, usually two for each artery. After perforating the rectum they run obliquely upward and backward to reach the nodes in the mesorectum. In their perirectal course they traverse several small nodes placed on the muscular layer and covered by the serosa coat of the rectum (pararectal nodes of Gerota). These nodes are found especially in the region of the ampulla, the lowest immediately above the levator ani. The superior nodes however may be found projecting underneath the serous coat and are minute. The true mesorectal nodes of considerable size are usually grouped around the superior hemorrhoidal artery and may be regarded as the true regional nodes of the superior region of the rectum. The flow of lymph in these channels is upward, although it is conceivable that a dam or block to the natural upward course might cause lymph to flow in a retrograde manner. Normally however the lymphatic drainage of the superior region of the rectum is only abdominal in direction (35) a point which cannot be too strongly emphasized. Whereas drainage from the inferior and middle regions of the rectum may be perineopelviabdominal with anastomoses in the posterior part of the vagina and the levator ani muscles, drainage from the upper part of the rectum has no direct anastomoses with pelvic organs unless it be by long tedious and unnatural retrograde flow down the surface of the rectum in the face of complete upward blockage as suggested previously.

Pathologic consideration. Having thus become well versed in the normal course of lymphatic drainage in and from the rectum it is now possible to appreciate more fully how malignant processes avail themselves of these channels. Discussion will be greatly facilitated by dividing the lymphatic system as a whole into intramural (from mucosa to serosa) and extramural (from serosa to regional nodes) components.

1 Intramural (Fig 1) Carcinoma of the rectum takes its origin from altered mucosal cells of the rectal lining usually stated as arising deep in the crypts of Lieberkühn. From this tiny focus it may spread either by direct

extension and invasion of small lymph meshes from its margins or directly through the thickness of the rectal wall. Marginal extension is greater and more rapid transversely around the bowel than through the rectal wall but even transverse extension is extremely slow. 6 months being the estimated time for carcinoma to travel approximately a quarter of the way around the lumen. Advance through the submucosal and muscular layers is equally slow and the serosal covering has usually not been reached until the growth has traversed three quarters of the circumference of the bowel or until some 18 months have elapsed. The circular and longitudinal muscles are pierced by radial channels thus giving free communication for malignant cells to travel between submucosal intermuscular and subserosal plexuses.

Cole was able to show that whereas carcinoma spread more widely in the submucosa than on the mucosal surface and still more widely in the muscularis there was no evidence of longitudinal permeation of the intestinal wall beyond the microscopic edge of the growth. Other studies appearing at approximately the same time all substantiated this view (5 22 30). Monsarrat and Williams demonstrated that as a rule longitudinal spread occurs only to the distance of about 2 centimeters above or below the gross mucosal edge of the lesion and that this invasion is greatest in the subserosal portion. In more recent years ample evidence (12 20 21 24 29) has accumulated indicating the improbability of any widespread dissemination along the course of intestinal walls comparable to the spread along the wall of the stomach that may occur in cases of gastric carcinoma. Apparently described anastomotic channels to any great distance are potential rather than actual. Leitch has expressed the belief that the lymphatics of the mucosa do not exist as a continuous plexus but are arranged in a decussating arborescent pattern from the collecting stems which pierce the circular muscular coat. Spread in the intermuscular lymphatics is just as limited (Fig 1). It may therefore be stated that intramural dispersion aligns itself closely with observed gross and microscopic extensions of the growth and plays no

part in the demand for extensive radical surgical intervention

2 Extramural. By far the most important mode of extension extramural spread has accordingly been the subject of most well directed research to date. Because of its supposedly widespread potentialities carcinoma at the rectosigmoid juncture has for the most part been subjected to the same treatment as has carcinoma lower in the rectum with removal of perianal skin rectal sphincter and the whole pelvic colon. Evidence in the literature combined with that of this study will demonstrate rather conclusively however that many growths high in the rectum lend themselves admirably to procedures far less radical than this and more acceptable to the patient but equally effective as far as the disease process is concerned. Close scrutiny and attention to detail will reveal a loophole which up to the present although noted by several investigators has failed to become widely recognized as such. True it is that a few surgeons have explored these possibilities to their own satisfaction but the majority either are unaware of the opportunities afforded or have been misled by existing pathologic studies.

In accord with anatomic findings Miles observed that malignant processes might extend in an upward lateral or downward direction although in his study he made no attempt to give the exact location of the lesions employing these various pathways. The common course is upward for it occurs in every case regardless of the site of the lesion from anus to sigmoid.

Lateral dissemination refers to that which courses along the levator ani muscles, the coccygeal base of bladder cervix or base of the broad ligaments to terminate in the internal iliac nodes. Miles has encountered such involvement in several cases both in that portion of the levators immediately adjacent to the bowel and far laterally near the pelvic walls. Gilchrist and David made similar observations in 4 cases of their series. Collier, Kay and MacIntyre in 6 and Gordon Watson and Dukes (18) in 1 case. That lateral dissemination may occur therefore is unquestioned and when one is dealing with low lying growths it must be given due consideration.

*Above the pectinate line

Downward invasion, as Miles used the term refers to spread along the inferior hemorrhoidal vessels through ischioanal fat and Alcock's canal, eventually to internal iliac nodes. Miles discussed 1 specimen removed by abdominoperineal resection in which the cancerous process had taken such a course. Other evidence that he presented was derived from records of postoperative recurrent growths occurring in the posterior wound. Whether these growths may be regarded as of true lymphatic origin or as occurring by direct invasion is a matter for debate. Gordon Watson and Dukes were undecided as spread in 2 of the 3 cases in which they noted ischioanal involvement appeared more likely to be by direct continuity.

The long unbroken chain of lymph nodes originating in the small pararectal nodes of Gerota deeply placed in the pelvis posterior to the rectum and extending through the larger superior hemorrhoidal group on into paraortic channels constitutes the upward and primary lymphatic drainage of the rectum. Neoplastic lesions situated anywhere within the pelvic colon sooner or later advance over this well traveled route. In the upper part of the rectum it is the *only lymphatic avenue available* for malignant invasion

unless, on further investigation, ideas concerning the importance of recently described perineural or perivascular (34) networks are confirmed.

This upward spread proceeds in an orderly manner so that on specimens from cases of advanced carcinoma there is a sequence of involved nodes stretching from the primary growth to the point of ligature of the inferior mesenteric vessels. This procession is usually from node to node but occasionally it is discontinuous with considerable intervening gaps, due to the presence of several upward tracks running so to speak over the same roadbed. Numerous paths course directly to nodes at the bifurcation of the superior hemorrhoidal vessels, a few to the junction of the superior hemorrhoidal and lowest sigmoidal vessels, by passing all nodes en route and others to the junction of the left colic and inferior mesenteric vessels. Thus on occasion, intervening uninvolved nodes have been observed, so that it is impossible to state which node is the highest seat of metastasis unless all to a considerable height have been examined. Examples of this pattern have been shown by Grinnell, Gabriel, Dukes, and Bussey (14), Wood and Wilkie as well as many others.

As no anastomoses of the lymphatics of the upper part of the rectum with those of pelvic organs exist, no lateral spread of carcinoma of the upper part of the rectum as described previously can occur via the lymphatics. Invasion by direct continuity may and does of course take place in direct proportion to the age of the growth.

Downward or retrograde spread along the course of the bowel through pararectal nodes although normally nonexistent may under certain circumstances be observed. In cases of advanced carcinoma in all probability beyond the realm of surgical cure when the superior hemorrhoidal and inferior mesenteric nodes all or in great proportion become clogged with extensive metastasis cancerous cells may take the course of least resistance downward in this instance over the same pathways which normally carry only one-way traffic—upward (17). Examples of this in the literature are rare and may be seen in Table I. There it will be noted that only 8 such cases have been observed the node at 4 centimeters below the lesion (Gilchrist and David) probably being the only true demonstration of such retrograde flow. If therefore retrograde metastasis is so rare and there are no other lymphatic anastomoses between the upper part of the rectum and pelvic structures should it not be reasonable that such facts be more widely applied in the surgical attack on lesions of the upper part of the rectum and rectosigmoid region? In order to be certain that such a stand could be taken on factual pathologic evidence and in the feeling that examination of the portion of the rectum and perrectal tissues lying between the lower part of the sigmoid and the insertion of the levator ani muscles would give the crucial answer long and tedious study was directed at this region by means of the following procedures.

MATERIALS AND METHODS

One hundred surgically removed rectums containing adenocarcinoma of the upper part of the rectum the rectosigmoid or the lower part of the sigmoid were obtained from the Division of Surgical Pathology of the Mayo Clinic. An attempt was made to secure only those specimens which represented far ad-

vanced disease so that the greatest possible spread of neoplastic cells might be contained therein. A choice from 2,206 such specimens was made only those removed by combined abdominoperineal technique being used to be assured of the maximum tissue for dissection.

That these specimens constituted a group containing most extensive malignant lesions is evidenced in several ways. All of the adenocarcinomas were of Duke's type C (11) that is all had metastasized to adjacent and regional lymph nodes. Grossly 99 were ulcerative and 1 was polypoid. Ulcerative lesions of the colon are the most malignant and invasive type. Twenty nine had advanced to perforation. Eighty three of the ulcerative lesions were annular. As to their site of origin in the upper part of the rectum and above 9.5 centimeters was the average distance from the lower gross mucosal edge of the lesion to the anorectal or pectinate line. This fact was ascertained by measurements of the formalinized specimens as well as by those recorded on the pathologist's report made at the time of operation and further corroborated by proctoscopic examination before operation.

It was originally intended to select the cases in equal number from each of the four grades of malignancy as classified by Broders thus making comparison of results more uniform than it would be otherwise. However as 75 per cent of rectal lesions are of low grade (1 and 2) it was impossible to secure enough specimens of the higher grades (3 and 4) which had not previously been used for other studies to fill in the required quota. Rather than sacrifice accuracy for statistics, all those lesions of higher grade which fulfilled the pre-

FIG. Case Location of the carcinoma with reference to the bowel, lymphatic and vascular systems (carcinoma, shaded area; involved nodes, black dots; uninvolved nodes, open dots)

viously stated requirements were chosen first—27 in number—and the difference up to 100—73 cases—was obtained from the more plentiful carcinomas of low grade (Table II).

Two methods for the complete examination of the lymphatic region of an organ are available. The injection method, the one most recently used and especially adapted to the examination of fresh tissues, is that described by Spalteholz and modified by Gilchrist and David. This type of investigation is accurate and has enabled its advocates to find many more nodes than they were previously able to locate by gross dissection of fresh specimens.

The other method is the more time-consuming and laborious gross dissection. This is the only method which can be used for tissues long immersed in formalin and may with application produce as satisfactory results as the injection method. Suffice it to say that the dissection method yielded results quite comparable to any other for in those 5 cases of this series in which all the nodes on the entire specimen were examined an average of 60 nodes per specimen was found, the largest number being 82, the smallest 44.

By gross dissection then each of the 100 specimens was minutely examined from the lower gross mucosal edge of the lesions present to the anus. Serial sections were cut each approximately 1 centimeter in width, the incisions beginning in the perirectal fat and being carried into the mucosa. The numerous slices thus produced were allowed to remain hinged on the mucosa so that accurate measurements could be taken concurrently. All lymph nodes were removed and each was carefully labeled not only as to its relationship to the lesion itself but also as to its position on the vascular tree. From these data all nodes were charted on diagrammatic sketches of the pelvic colon which were drawn to scale and on which each lesion had previously been outlined also according to scale. An average of 11 nodes per specimen was found between the limits outlined previously, the largest number being 53, the smallest 2. A total of 1,339 nodes was found during the course of the whole study including nodes examined behind and above the lesions in the few cases indicated later.

Each node was then subjected to microscopic examination by the frozen section technique used in this case for screening those nodes metastatically involved from those uninvolved. All nodes containing any evidence of cancerous cells were further sectioned and stained with hematoxylin and eosin for study. Those found to be free from involvement were not examined further. One thousand four hundred seventy nine sections were made.

RESULTS OF STUDY

In 64 cases there was no spread distal to the lower gross mucosal level of the lesion but in 36 cases there was distal spread. In 27 of the 36 cases the nodal involvement was within the first centimeter and no lower; in 6 it was between 1 and 2 centimeters but no lower; and in 1 case each it was between 2 and 3 centimeters, 3 and 4 centimeters, and 6 and 7 centimeters.

All those cases in which there were positive nodes from the lesion to 2 centimeters but no lower were considered to be of no particular significance for the reason given previously in the section on intramural spread. It will be

remembered that as malignant invasion proceeds from the mucosal to the serosal surface of the intestinal wall it does so in a more or less triangular fashion the base of the triangle being placed longitudinally along the long axis of the bowel in the perirectal fat at the serosa. In advanced lesions such as these the greater involvement in the perirectal fat and serosa as compared with involved mucosa always extended 1 centimeter below and above the longitudinal diameter of the lesion as measured on the mucosa frequently extended to 2 centimeters in either direction and was occasionally seen at 3 centimeters. As a consequence all nodes within the first centimeter were found to be imbedded in carcinomatous tissue so that their removal for microscopic examination was in reality of academic interest only. Four of the 6 cases in which lymphatic spread was 1 to 2 centimeters were in this same category. In the other 2 cases the involved nodes were immediately adjacent to but not actually imbedded in carcinomatous tissue. The nodes from the 3 cases in which nodal involvement was more distal however were further removed from directly involved tissues although malignant extensions from the local growth were considerably closer than the indicated distance as measured from the lower mucosal level of the lesion. In summary therefore of the 100 cases in which the tissues were thoroughly examined only 3 could be classified as exemplifying true retrograde metastasis of any significance.

The obvious question now arises. Why did retrograde lymphatic permeation occur in 3 cases and not in the others? This problem entailed the re-examination of those tissues in which retrograde spread had occurred. For the sake of obtaining more complete evidence and also because 2 of the 6 cases with spread to 2 centimeters might be construed as instances of downward spread all cases in which the distance was more than 1 centimeter were included in this additional study. In the same manner as has already been described all remaining nodes on the 9 specimens in question except as indicated were removed and subjected to sectioning and charting. A detailed report was prepared for each case consisting of both clinical and

Fig. 3. Case 2. For explanation see legend of Figure 2.

pathologic features as they applied in each instance.

REPORT OF CASES

CASE 1. A white woman, 61 years of age, registered at the Mayo Clinic July 14, 1917, with a chief complaint of rectal stoppage. A detailed history revealed 1 year of rectal bleeding, suprapubic uneasiness, ribbon like stools and finally almost complete obstruction and loss of 20 pounds (9.1 kgm.). Physical examination gave negative results except for a large, hard, fixed encircling mass high in the rectum. On July 23, 1917, one stage perineoabdominal resection was performed. During the operation a small suspicious nodule was felt in the liver. The patient was dismissed from the clinic on August 31, 1917, after an uncomplicated recovery. The last report indicated her death in November, 1917. No details were given. Grossly the surgical specimen contained a very extensive annular ulcerative lesion 7 by 6 by 4 centimeters; mucosal measurement 6 centimeters above the pectinate line. A total of 70 lymph nodes were found. Microscopically the lesion was an adenocarcinoma, grade 4 (Broders). For distribution and involvement of nodes see Figure 2. The lowest involved node was found between 1 and 2 centimeters below the lower mucosal edge of the lesion.

CASE 2. A white man, 36 years of age, registered at the clinic April 25, 1934, with a chief complaint of constipation after 6 months of blood-streaked, mucoid rectal discharges, dull abdominal aches and pains, increasing constipation and loss of 7 pounds (3.2 kgm.). Physical examination gave essentially

Fig. 4. Case 3. A cross section through the perirectal tissues at about the midportion of the lesion as illustrated in Figure 5. The solid carcinomatous area on the left corresponds to the double crosshatched area in Figure 5. The two nodes to the right above are also represented in Figure 5. They were found to be completely replaced with cancer cells. The block to the upward flow of lymph is obvious.

Fig. 5. Case 3. For explanation see legend of Figure 4. Compare with Figure 4.

negative results except for a large encircling lesion especially prominent on the posterior wall high in the rectum. This lesion was verified by proctoscopic examination. On May 1, 1934, one stage combined abdominoperineal resection was performed. At operation the liver was noted as clear. The patient was dismissed from the clinic on May 24, 1934, after an uncomplicated recovery. The last report indicated death in December, 1935, with extensive metastasis about the colonic stoma, abdomen and liver. Grossly the surgical specimen contained a huge ulcerative lesion 15 centimeters in diameter, mucosal measurement 10 centimeters above the pectinate line. A total of 55 nodes were found. Microscopically the lesion was a colloid adenocarcinoma, grade 4 (Broders). For distribution and involvement of nodes see Figure 3. The lowest involved node was found between 1 and 2 centimeters below the lower mucosal edge of the lesion.

CASE 3. A white man, 50 years of age, registered at the clinic July 22, 1936, with a chief complaint of "bloody diarrhea." For 1 year he had had bloody rectal discharge and dull abdominal cramps with a final weeks of constant pain and constipation. He had lost 40 pounds (18.1 kgm.). Physical examination revealed a huge, hard, irregular cauliflower-like mass in the rectum which was verified by proctoscopic examination. On July 27 and August 24, 1936, two stage combined abdominoperineal resection was performed. The liver was clear but there was extensive spread to the bladder and around the left ureter. The patient left the clinic in September 12, 1936,

without dismissal but recovery had been uncomplicated. The last report indicated death in April, 1937, but no details were given. Grossly the surgical specimen contained an extensive annular ulcerative lesion 9 by 8 by 5 centimeters, mucosal measurement 6 centimeters above the pectinate line. Thirty-two nodes only were removed and examined; the others were allowed to remain *in situ* for photographic evidence as shown in Figure 4. Microscopically the lesion was an adenocarcinoma, grade 2. For distribution and involvement of nodes see Figure 5. The lowest involved node was found between 2 and 3 centimeters below the lower mucosal edge of the lesion.

CASE 4. A white woman, 3 years of age, registered at the clinic August 22, 1938, with a chief complaint of "diarrhea." For 3 months she had had colicky pains in the left lower quadrant associated with diarrhea, occasionally bloody. She had lost 13 pounds (5.9 kgm.). Physical examination gave negative results except for a mass with some fixation of the bowel on rectal examination. Proctoscopically a lesion was found involving the right and anterior walls of the lower part of the sigmoid colon. On August 29 and October 3, 1938, two stage combined abdominoperineal resection was performed. The liver was noted as clear but there were implants throughout the pelvic peritoneum. The patient was dismissed from the clinic November 19, 1938, in good condition after a mild postoperative urinary infection. The last report indicated death on April 7, 1941, from a recurrence. Grossly the surgical

Fig. 6 Case 4. For explanation see legend of Figure 2

specimen contained a perforated annular ulcerative lesion 4 by 3 by 3 centimeters mucosal measurement 16 centimeters above the pectinate line. A total of 84 nodes were found. Microscopically the lesion was an adenocarcinoma grade 3 (Broders). For distribution and involvement of nodes see Figure 6. The lowest involved node was found between 6 and 7 centimeters below the lower mucosal edge of the lesion.

The question arises in this particular case whether all the involved nodes shown below the lesion in Figure 6 represent true *retrograde* spread. As the lesion itself was in the lower part of the sigmoid, a portion of the colon still maintaining a mesentery, it seems probable that normal flow of lymph had occurred over the two lower rectosigmoid arcades, both of which lie below the lesion. This is consistent with the lymphatic drainage of the colon proper which differs from rectal drainage in that it may proceed along the axis of the bowel in either direction from a lesion until a vascular arcade has been reached at which point it courses in through the mesentery to large midline plexuses of nodes. In that event only the four lower carcinomatous nodes, a span of about 3 centimeters, would represent true *retrograde* involvement. However, as

Fig. 7 Case 5. For explanation see legend of Figure 2. Compare with Figure 8.

the original premise and conditions of study included all nodes below the level of the lesion, all the nodes in Figure 6 will be considered as examples of *retrograde* spread.

CASE 5. A white woman, 57 years of age, registered at the clinic November 13, 1939, with a chief complaint of increasing constipation of 8 months duration, bloody stools and the continual sensation of a full rectum. She had lost 17 pounds (7.7 kgm.). Physical examination gave negative results except for a large rectal mass which was confirmed by proctoscopic examination. On November 17, 1939 and January 19, 1940, two stage combined abdomin-

Fig. 8. Case 5. Lesion from serosal surface. Because of the absolutely solid nature of the infiltrating carcinoma in the perirectal fat it was deemed unnecessary to attempt dissection of the nodes behind and above the lesion in this case.

Fig 9. Case 6. Lesion from serosal surface split and laid open, showing the solid nature of the infiltrating cancer (see report of Case 6)

operineal resection was performed. The liver was noted as clear. The patient was dismissed from the clinic March 18, 1940 in good condition after a complicating postoperative thrombophlebitis. The last report indicated death on April 12, 1941 from a recurrence. Grossly the surgical specimen contained a large annular ulcerative lesion 7 by 6 by 5 centimeters mucosal measurement 9 centimeters above the pectinate line with two polyps one 5 centimeters below the growth and one 1 centimeter above it. Twenty-seven nodes only were removed and examined the others were allowed to remain *in situ* for photographic evidence as shown in Figure 8. Microscopically the lesion was a colloid adenocarcinoma, grade 2 (Broders). For distribution and involvement of nodes see Figure 7. The lowest involved node was found 3 to 4 centimeters below the lower mucosal edge of the lesion.

CASE 6. A white man, 52 years of age, registered at the clinic December 2, 1940 with a chief complaint of weight loss. For 3 months he had had rectal bleeding, urgency, and bouts of diarrhea and constipation. He had lost 17 pounds (7.7 kgm.). Physical examination revealed a "mass felt high in the rectum" which was confirmed by proctoscopic examination. On December 7, 1940 one stage combined abdominoperineal resection was performed. The liver was clear to palpation. The patient was dismissed from the clinic January 2, 1941 in good condition. The last report on June 18, 1941 stated that he suffered from backache and pain down both legs. There has been no further communication. Grossly the surgical specimen contained an ulcerative lesion 5 by 4 centimeters with direct extension

Fig. 10. Case 6. For explanation see legend of Figure 9. Compare with Figure 9.

into perirectal tissues forming a mass 8 by 6 centimeters. The lesion was 8 centimeters above the pectinate line. Only 9 nodes were removed and examined the others being allowed to remain *in situ* for photographic evidence as shown in Figure 9. Because of the absolutely solid nature of the infiltrating cancer throughout all perirectal tissues behind and above the lesion it was not considered necessary to isolate nodes in order to demonstrate their blocked nature. Figure 9 demonstrates adequately the large dam-like mass extending around the bowel and effectively shunting advancing carcinoma in a retrograde direction. Microscopically the lesion was an adenocarcinoma, grade 3 (Broders). For distribution and involvement of nodes see Figure 10. The lowest involved node was found 1 to 2 centimeters below the lower mucosal edge of the lesion.

CASE 7. A white woman, 53 years of age, registered at the clinic June 6, 1941 with a chief complaint of "bloody diarrhea" of 5 months with spells of low backache. She had not lost weight. Physical examination demonstrated a large, nodular mass on the left posterior wall of the rectum which was confirmed by proctoscopic examination. On June 10 and August 8, 1941 two stage combined abdominoperineal resection was performed. On September 15, 1941 the patient was dismissed in good condition after complicating thrombophlebitis, pulmonary embolism and pneumonia between stages of the resection. September 10, 1941 a plastic operation was performed on the colonic stoma. From September,

Fig. 1. Case 7. For explanation see legend of Figure 2. Compare with Figure 12. The small black rectangle is discussed in the report of Case 7.

1942 to April 1943 four courses of roentgen therapy were given. The last report on September 23, 1943, showed the presence of some pelvic pain. Grossly the surgical specimen contained an annular ulcerative perforating lesion 5 by 4 by 1.5 centimeters, mucosal measurement 8 centimeters above the pectinate line. A total of 23 nodes were found. The small black rectangle shown on Figure 11 between 1 and 2 centimeters below the growth represents tissue removed under the impression that it was a lymph node. Careful microscopic examination indicated that very little lymphoid tissue could be identified. There was however a small blood vessel with a small region of carcinomatous cells immediately adjacent, which may have represented a tiny node completely replaced by cancer or may have been a rare demonstration of perivascular spread (Fig. 12). In any event it was impossible to show adequate evidence of a block above this lesion as only 4 of the 14 nodes behind and above the lesion were involved. Microscopically the lesion was an adenocarcinoma grade 1 (Broders). For distribution and involvement of nodes see Figure 11. No involved nodes were found below the lower mucosal edge of the lesion.

CASE 8. A white man 62 years of age registered at the clinic September 8, 1941, with a chief complaint of "alternate constipation and diarrhea. One year of constipation, rectal bleeding, painful movements and a loss of 12 pounds (5.4 kgm) were the main symptoms. Physical examination disclosed a high fixed lesion in the rectum which was verified

Fig. 12. Case 7. Possible perivascular lymphatic spread as discussed in report of Case 7. The vessel is cut longitudinally the lumen appearing as a strand of cells in the upper right corner. $\times 100$.

by proctoscopic examination. On September 25 and October 27, 1941, two stage combined abdominoperineal resection was performed. The liver was clear. The patient was dismissed on December 4, 1941, in good condition despite a mild urinary infection (postoperative). The last report on July 16, 1943, indicated a loss of 15 pounds (6.8 kgm) but no other evidence of recurrence. Grossly the surgical specimen contained an annular ulcerative perforating lesion 7 by 6 centimeters, mucosal measurement 12 centimeters above the pectinate line. A total of 56 nodes were found. Microscopically the lesion was an adenocarcinoma grade 4 (Broders). For distribution and involvement of nodes see Figure 13. The lowest involved node was found between 1 and 2 centimeters below the lower mucosal edge of the lesion.

CASE 9. A white woman 39 years of age registered at the clinic September 17, 1942, with a chief complaint of constipation. For 2 years she had had recurrent rectal bleeding, pain high in the rectum and increasing constipation. She had lost 8 pounds (3.6 kgm). Physical examination revealed a palpable mass high in the rectum which was confirmed by proctoscopic examination. On September 23, 1942, one stage combined abdominoperineal resection was performed. The liver was clear. On October 16, 1942, a course of roentgen therapy was given. The patient was dismissed October 20, 1942, in good

FIG. 3. Case 8. For explanation see legend of Figure 2.

FIG. 4. Case 9. For explanation see legend of Figure 2.

condition after a mild urinary infection. The last report was on September 6, 1913, when a check up at the clinic revealed no evidence of recurrence. Grossly the surgical specimen contained an annular, ulcerative lesion 5 by 4 by 2 centimeters, mucosal measurement 7 centimeters above the pectinate line. A total of 44 nodes were found. Microscopically the lesion was an adenocarcinoma, grade 4 (Broders) with squamous-cell metaplasia. For distribution and involvement of nodes see Figure 14. The lowest involved node was found between 1 and 2 centimeters below the lower mucosal edge of the lesion.

SUMMARY OF REPORT OF CASES

Nine cases of carcinoma of the rectosigmoid demonstrating possible retrograde spread have been presented in detail with all pertinent clinical, surgical, and pathologic data. In 5 cases all the nodes on the specimens were examined microscopically and in each case approximately two thirds of the nodes found behind and above the lesion were so completely clogged with cancer cells that any further drainage of lymph through their sinuses seemed impossible (Cases 1, 2, 4, 8, 9). In 1 case only a portion of the lymph nodes were examined. More than three quarters of these nodes found behind and above the lesion were completely involved with carcinoma and photographic evidence was sufficient to show

that all other nodes were likewise involved (Case 3). In 2 cases the tissues were so extensively frozen in cancer that it was deemed unnecessary to show any further evidence of their complete involvement than that demonstrated photographically (Cases 5 and 6). Case 7 remains an enigma. Whether the retrograde spread demonstrated in this specimen represented an involved node or was a rare instance of perivascular lymphatic permeation is unanswerable. In any event there was not the high percentage of nodal involvement behind and above the lesion considered to be necessary to form a block to the upward flow of lymph.

It may thus be concluded that, when retrograde lymphatic spread down the course of the rectum and its ensheathing structures occurs, it does so as the direct result of a block occurring somewhere across its upward channels and that the contained lymph stream is merely seeking the course of least resistance, all normal upward avenues for drainage being closed.

COMMENT

For confirmation of the mass of evidence against any normal retrograde dissemination

of neoplastic cells from malignant growths in the upper part of the rectum and above presented in the preceding pages, it is interesting to refer to the pathologic data which have thus far accumulated in the literature. Table I represents a complete summary of such data.

In more than 239 of the 507 cases from the literature in which the removed tissues were completely examined nodal metastasis was observed to occur. Of these only 8 gave evidence of an involved node below the level of the lesion itself. As the lower level of the lesion was not defined in each case the actual distance of these nodes from the lesion can only be conjectured. Nevertheless, in 7 of the 8 cases there was no spread below the 2 centimeter level which when interpreted in the terms outlined in this study remains insignificant. One case therefore that of Gilchrist and David in which the involved node was 4 centimeters below the lesion represents the total significant retrograde lymphatic flow from carcinoma of the rectum contained to date in the literature. When combined with results given previously for our cases only a fraction over 1 per cent of far advanced malignant growths of the pelvic colon may be expected to metastasize in a retrograde fashion. If this obtains so rarely in cases in which the patient is already doomed to early demise one cause of the advanced nature of the lesion one may be justified in making the statement that retrograde lymphatic metastasis never occurs from growths still in the stage of reasonable operability.

Perusal of Table I will further demonstrate that about a half of all neoplastic growths of the rectum when seen at operation do not as yet have nodal involvement. To be certain that this was true over the years from which the cases in this study were drawn Table III was constructed. There it will be noted that in 59 per cent of the cases there was no nodal involvement. To be sure had all these cases shown from 1916 to 1942 inclusive been subjected to intensive study no doubt the 59 per cent would drop below 50 per cent as recent published studies in which the data were so treated indicate (8, 16). However the 1 per cent incidence of retrograde lymphatic spread in advanced cases when adjusted to include

TABLE III—NODAL INVOLVEMENT IN CARCINOMA OF THE UPPER PART OF THE RECTUM, RECTOSIGMOID AND SIGMOID CASES IN WHICH THE LESION WAS RESECTED AND GRADED (1916-1942 INCLUSIVE)

Nodes	Total		Grades and (Broders)		Grades 3 and 4 (Broders)	
	Number	Percent	Number	Percent	Number	Percent
Positive	910	4	570	37	3	63
Negative	246	50	1, 60	63	37	35
Total	8, 305	100	2, 133	100	40	100

the average type of carcinoma occurring in the rectum (approximately 50 per cent with nodes uninvolved) then drops to less than 0.5 per cent and as such becomes negligible. Should it not be possible therefore in the light of pathologic evidence and in view of the many recent advances in colonic surgery to preserve the lower part of the rectum in a very considerable number of cases in which the patients heretofore have been deprived of normal sphincteric control (10)? Perhaps time alone will provide the answer but certain it is that such attempts are more than justified and should engage the attention of all surgeons who endeavor to relieve the encumbrances of rectal neoplasms.

CONCLUSIONS

The following significant features deserve a word of emphasis in conclusion.

1. Because carcinoma of the rectum is primarily of a low grade of malignancy the disease tends to remain localized for a considerable period and thus lends itself admirably to surgical attack.

2. As carcinoma of the upper part of the rectum and the rectosigmoid has only one normal channel for lymphatic spread—upward—provided local growth by direct extension has not incorporated neighboring organs, it should be suitable for radical segmental resection with preservation of the rectal sphincter and restoration of the normal continuity of the bowel.

3. Radical segmental resection implies the removal of a wide section of bowel together with its complete node-bearing region just as the abdominal portion of a combined abdomi-

noperineal resection is now performed (technique to be reported)

4. Section of the bowel must be at least 2 centimeters below the lower palpable edge of the lesion to satisfy pathologic requirements. The technical requirements in the successful performance of an adequate anastomosis in this area also involve the removal of such an amount of tissue because of the size and position of neoplasms so located.

5. It has been demonstrated that even in far advanced cases of carcinoma in this region retrograde spread along the course of the bowel occurs to any degree in only 1 per cent.

6. When such retrograde spread can be demonstrated it is an indication that upward normal channels have been blocked.

7. When these facts become more generally appreciated and the technical procedures required for such surgery are subjected to refinement many sufferers from neoplastic lesions in the rectosigmoid region will enjoy a normal postoperative existence without the psychologic—to say nothing of the anatomic—detriments of a permanent artificial anus.

RECTAL STRICTURES DUE TO LYMPHOGRANULOMA VENEREUM

With Especial Reference to Pauchet's Excision Operation

LOUIS T WRIGHT MD F.A.C.S., BENJAMIN N BERG MD F.A.C.S.
JOEL V BOLDEN M.D., and W ADRIAN FREEMAN MD New York, New York

DESPITE the abundant and ever increasing literature on the general subject of lymphogranuloma venereum surgeons still differ greatly in their opinions as to the best method of treatment of lymphogranulomatous strictures of the rectum. The use of sulfonamides and more recently of penicillin has lessened secondary infection in these cases, but in no way has it decreased in certain cases the tendency of the disease to progress and develop fibrous tissue that cicatrizes and produces marked rectal stenosis.

An example of such a patient is presented through the courtesy of Dr Marshall E Ross, of the gynecological service with whom one of us (L T W) examined the patient in consultation.

S D colored widow 45 years of age a domestic, was seen August 7 1937. She complained of a swelling about the vulva, which began as a small pimple 18 years before, gradually grew larger and was painful. In 1935 because of constipation and pain on defecation she was treated elsewhere with deep x ray therapy. The vulval swelling immediately increased in size she had lost weight, was easily fatigued and had pain in the perineum. The Frei test was strongly positive and a biopsy of tissue from the vulval swelling which also involved the anus showed marked fibrosis with round cell infiltration and some plasma cells. Examination on contraction in August, 1937 revealed elephantiasis of the vulva involving the anus, a stricture of the vagina, a rectovaginal fistula and a marked annular stricture of the rectum 1 centimeter above the internal sphincter. She was advised to have a colostomy operation but refused. She subsequently moved to Connecticut, and in reply to a follow-up letter her physician wrote under date of November 18 1938 as follows:

When first examined she had large sloughing pedunculated granulomatous ulcerated overgrowths

From the Surgical Service of the Harlem Hospital, Dr Louis T Wright, director.
Founders Lecture, Medicosurgical Society of the District of Columbia, November 5, 1943.

Involving the labia majora and minora extending from the pubis in front and including the rectal sphincter behind. The rectal sphincter had been entirely destroyed and the septum between the vagina and the lower rectum was destroyed. A complete excision of the growth from the pubes to the coccyx was done and the wound was closed except for drainage at the angles. For about 2 weeks she did very well and then the wound broke open somewhat leaving a granulating surface, which was skin grafted. The skin graft took for the most part. She left the hospital and was up and around feeling fairly comfortable.

But the wound gradually broke down and signs of intestinal obstruction developed. Stricture ever narrowing could be felt at the junction of the rectum and sigmoid. As it seemed evident that the infection still persisted in the lower rectum and around the stricture and in the pelvis where a large mass could be felt it was decided to do a laparotomy. At laparotomy a large dermoid growth of the right ovary the size of a grapefruit was found. This growth was removed and in addition a hysterectomy double salpingo-oophorectomy and colostomy were done bringing the sigmoid out through a stab wound in the left flank. A resection of the lower segment of the sigmoid and rectum including the stricture was also done. The patient withstood the ordeal remarkably well. She recovered and went home. Later she returned and at that time she had developed squamous cell carcinoma at the left edge of the vagina at the junction of the vaginal mucosa and skin. Radical needles were inserted in this growth and the cancer disappeared and again she returned to her home.

She returned in a few weeks with a crater about 2 inches deep burrowing into the left upper leg toward the femoral artery and the left side of the vagina was involved in this crater. Numerous sinuses discharged pus which oozed from openings throughout the floor of the crater so that as it was impossible to incise all these to give adequate drainage was removed the crater looked quite healthy and was healing satisfactorily but the patient became increasingly thin and emaciated and died.

Autopsy was refused so the real cause of death was not determined although it would seem that it was probably caused by urinary involvement from extension up along the ureters.

" The Frei antigen was continued here for some time and in addition two courses of sulfanilamide and antisyphilitic therapy for weeks were given. Before I saw her deep x ray therapy had been applied to the lesion. It was my opinion that the lesion might be cured by wide excision of the affected area and this is still my opinion. It was my belief that operation had been radical enough but apparently some of the disease was left behind and gradually progressed."

This case illustrates the progressive nature of the disease its seriousness, the later development of carcinoma with a fatal termination despite all known methods of treatment, including an abdominoperineal resection which here was obviously performed too late to be of value.

HISTORICAL REVIEW

It seemed worth while therefore to review briefly the historical background of the disease and excision procedures and to report 26 personal cases in which we have resected the rectum preserving the anal sphincter.

Lymphogranuloma venereum was isolated in 1913 as a separate clinical entity by Nicholas, Favre and Durand. Frei (6) greatly advanced interest in the disease when he introduced his intradermal diagnostic test which has proved to be specific. Hellerstrom showed that lymphogranuloma venereum was due to a filterable virus. Frei and Koppel (8) and Bensaude and Lambling proved that the majority of non neoplastic strictures of the rectum were due to this disease.

Larsen in 1849 described inflammatory strictures of the rectum in 11 women.

The first case of excision of the rectum for stricture was reported in 1864 by Glaser. His patient had a recurrence and 2 years later he had to make a colostomy. During the next 20 years several surgeons reported a few additional cases but because the operation was difficult and there were recurrences, the operation was discarded.

To Professor Henri Hartmann (10) of Paris, goes the credit for recognizing the seriousness of the disease and giving it careful and prolonged study in all of its surgical aspects. Early in his career Hartmann performed 16 external rectotomy operations. In no case did it cure the patient, but it relieved

them and all of them continued to suppurate and suffer a certain degree of incontinence. For this reason he gave up the operation. Later in 1895 Hartmann and Queiro (13) reported a series of 35 cases, most of them their own in which no excision of the stricture was done. They concluded that the operation of excision seemed to tend toward ultimate recovery. Since then for a period of approximately 40 years Hartmann has advocated resection and has successfully performed the operation in many strictures of the rectum. Careful histopathological studies were made of each resected specimen. In 1930 he reported excision operations upon 66 patients for rectal stricture. An abdominoperineal amputation was made in 6 cases and 3 patients died a mortality of 50 per cent. At first the perineal amputation was made without considering the sphincters and in 56 cases the results were only fair. One of 9 such patients died. Only 4 patients could be followed and 2 of them were cured. The best results were made by intrasphincteric amputation, and he stated "Real cures can be obtained in most strictures not accompanied by profuse suppuration. Among 27 such amputations there were only 2 deaths, and he states

"It was possible to follow 31 of the patients. There was a recurrence of the stenosis in 3 cases and a colostomy was necessary in 1 year, 4 years, and 6 years after amputation. Eight patients were improved but continued to suppurate and one of them died at the end of 13 years with diarrhea and swelling of the face, probably due to amyloid degeneration. Twenty patients were cured of their rectitis and there was no stenosis or separation of the mucosa. An endoscopic examination of the rectum showed that the mucosa was normal in appearance. All of these patients were continent, but the continence was not absolute and when they had diarrhea they were not able completely to retain their feces. Two of the patients complained of having moisture around the anus.

In Hartmann's *Chirurgie du Rectum* published in 1931 he has an extensive chapter entitled *Rectitis Stenosantes* which includes his experiences and many detailed case histories, and he concludes

"The first thing, in contradiction with the recognized opinion, is that excision of the rectal stenosis may give complete and definite recovery. Colostomy indicated from the first, when the rectitis

is abundant with suppuration and complicated with multiple fistulas ameliorates the state of the patient considerably and makes life bearable. It may be wholly insufficient if the suppuration continues abundantly and above all if hemorrhages take place.

In 1926 De Roche reported 21 cases of fibrous strictures of the rectum in which resection was done with one operative death. Follow up results were obtained in 8 cases which were as follows after 1 year 1 suppurated, 1 had to be dilated 3 had relapsed and 3 had maintained excellent results.

Dimitriu and Stoia in 1933 reported 25 cases of abdominoanoanal excision with preservation of the sphincter mechanism. Nineteen patients were cured 3 died and 3 recurred.

It seems that French surgeons were the first to recognize the essential need for surgical treatment of serious strictures of this type. The surgical treatment aimed at (1) correction of the stenosis, and (2) extirpation of all diseased tissue to prevent spread.

Lockhart Mummery who represents the best English opinion in his textbook in 1934 states

If a stricture is noted near the anus very excellent results in suitable cases are obtained. A modification of Whitehead's operation is all that is necessary to get rid of the stricture. It is not easy as a fibrous tissue outside the stricture prevents the separation of the mucosal membrane in the normal manner and this renders it difficult. When the stricture is more than one inch from the anus, the method is not possible and a formal excision similar to that for malignant disease is necessary. The operation of excision of a portion of the rectum for nonmalignant stricture is not one to be lightly undertaken, as a stricture serious enough to warrant removal of this portion is almost certain to be associated with a dense amount of fibrous tissue in the surrounding parts, which makes the anatomy quite abnormal, and may cause great difficulty in separation of the rectum.

In none of his published works has Lockhart Mummery shown any enthusiasm for the excision operation as a method of treatment for rectal strictures.

Martin, in 1933 reported a series of 227 rectal strictures in negro women and concluded that the disease is incurable and tends toward an inevitable fatal termination, but nowhere does he suggest a definite method of

treatment. Spiesman Levy, and Brotman in a study of 183 strictures from the Cook County Hospital reported 2 resections one done by Davison and one by McNealy.

Edwards and Kindell reported satisfactory results in 6 cases in which they made a preliminary colostomy and later did a perineal extirpation of the diseased rectum according to the technique described by Lockhart Mummery for rectal malignancy.

Barber and Murphy from Bellevue Hospital reported 35 cases of resection 4 were one stage sacroperineal and 31 were abdominal colostomies followed by sacroperineal resections. Five of their 35 patients died, which gave a hospital mortality of 14.3 per cent. These 5 were extreme cases and there were no immediate postoperative deaths. They stated that in 2 patients who had had an original colostomy the colostomy ceased to function after the granulomatous process crept up to and involved the sigmoidostomy stoma. They made a permanent abdominal anus in their advanced cases. Two cases showed carcinoma.

Woods and Hanlon in 1944, reported from the Cincinnati General Hospital 35 cases treated by rectosigmoid resection. In analyzing 192 cases of rectal stricture they stated that 'colostomy has been usually employed at an advanced stage with no constant success in arresting the disease. They performed colostomy without resection in 34 cases 2 died of postoperative complications radical resection was performed in 35 cases. With no operative deaths, abdominoperineal resection was performed 23 times with good results in 20 of the 23 cases. In the perineal resection of the Lockhart Mummery type in 9 cases the results were good in 5 poor in 2 and fair in 2. They emphasize, however that the resection operation is a procedure of considerable magnitude and should be undertaken only after conservative methods fail. They conclude though, that the abdominoperineal resection is a satisfactory operation and that they have never seen resolution of firm fibrous strictures.

From the above résumé and from a study of other available literature, it becomes apparent that the general attitude in this country and in England up until about 5 years ago was

that these cases were best treated by dilatation if the lesion was apparently mild, and by a permanent colostomy if the patient's condition was at all serious. Only in the reports from the Baltimore City Hospital by Edwards and Kindell from the Bellevue Hospital by Barber and Murphy and from the Cincinnati General Hospital by Woods and Hanlon have American surgeons shown any indication of their appreciation of the definitive treatment of this serious malady.

Our own experience coincides with that of Hartmann, namely that drugs dilatation and other simple procedures can in no way take the place of radical surgery in the treatment of advanced rectal strictures. The increased tendency on the part of some American surgeons to use excision as an operation of choice indicates their recognition of this fact.

At Harlem Hospital we have had 4 deaths following dilatation of rectal stricture while Woods and Hanlon report 7 deaths following the same procedure at the Cincinnati General Hospital. There is no doubt that many deaths as a result of bougie or instrumental dilatation of benign strictures of the rectum have occurred throughout the country but the cause of death has not been so reported.

Licione was the first to report carcinoma as a sequela of rectal stricture; he recorded 2 cases. Woods and Hanlon reported 3 cases, and 3 cases were reported by Barber and Murphy from the Bellevue Hospital. We found records of 3 cases in the hospital and one of us (L. T. W.) observed another case in private. It is noteworthy therefore that the incidence of a superimposed carcinoma of the rectum upon this apparently benign lesion occurs much more frequently than is supposed.

We have used, in the treatment of these strictures every form of mild treatment excepting x ray and this includes finger dilatation dilatation with Wales bougies, posterior proctotomy in some instances, in rare cases Keller's tunnel grafts sulfonamides, Frei antigen diathermy carbon dioxide snow none of these availed but little in the serious cases. We have found that posterior proctotomy operations, followed by bouginage, give temporary relief but that in the final analysis they serve only to spread the disease

and to make the stricture more rigid. Levy Holder and Bullowa, from our out-patient department, reported good results with sodium sulfaniloyl sulfanilate but the end-results have not been up to expectations in fact, some of the patients so treated are still coming back to the clinic and no doubt others have wandered off to other hospitals.

Many of the unconsidered factors in the difficulties of the palliative methods of treatment of strictures particularly in colored people are due probably to the fact that certain fibrous tissue reactions such as keloids and elephantiasis, are predominant in colored races. Rosser used this observation to explain the frequency of rectal strictures in negroes and postulated that they had a tendency toward fibroblastic tissue hypertrophy. This has been our experience.

Colostomy has been the ultimate procedure used in most clinics when the patient's life is obviously threatened. Many colostomies have been performed by us for relief of benign rectal strictures in females. Seven patients entered the hospital with colostomies done elsewhere; 5 patients showed a stricture of the colostomy opening after operation; 4 patients needed another colostomy. Some authors have claimed that colostomy alone tended to cure or soften the strictures. This is, of course, absurd. It is true that ulceration, secondary infection and toxemia resulting therefrom have been lessened by diversion of the fecal stream but we have never found that colostomy cured a real fibrous stricture of the rectum.

Experienced surgeons know that colostomy *per se* is not without certain specific dangers. This is true even when performed by surgeons of ability and great experience. These dangers are first, stenosis or a stricture of the colostomy opening. Such stricture occurs a few months or a few years after the artificial anus has been made. It happened in 5 of our cases and in 2 patients admitted from other hospitals. The second danger is retrograde or antero-grade herniation of the bowel. This herniation occurs when the opening in the abdominal wall is too large. If the proximal segment of the bowel is mobile an antero-grade herniation occurs. This occurred in 4 of

WRIGHT ET AL. RECTAL STRICTURES

our cases. If the distal end of the sigmoid is mobile a retrograde herniation occurs this happened in 3 of our cases and in 2 patients admitted from other hospitals. It is impossible to foretell whether any of the above complications will or will not occur following a colostomy. We have seen secondary operations performed and deaths occur because of all of the above complications. Therefore, it is our conclusion that colostomy although successful in some instances, is not and cannot be the best surgical answer to this problem. At best, it can serve only as a definitive method of treatment when no other rational option is available. Aside from the surgical complications many patients will go on to their deaths and refuse help rather than have an artificial anus, and particularly is this true in young women in the early decades of life. It is likewise true that when the disease involves the entire rectum or extends up to the sigmoid, one has no choice but to advise a permanent colostomy with or without a sacroperineal resection otherwise the patient unquestionably dies.

We have seen patients with dangerous and serious sequelae which followed colostomy operations, even in the hands of experts. When there was marked stenosis of the colostomy opening—and these cases are numerous in colored people—we have had to perform another colostomy in the transverse colon. Many strictured colostomy openings develop abscesses and fistulas. We have also had to treat some of the so called perineal resections done at other hospitals for serious late infection, which in one instance, extended up to the fifth dorsal vertebra (Figs 1 and 2).

The seriousness of this disease is further emphasized by Kassebohm and Schreiber who have reported from the Obstetrical Service of Harlem Hospital deaths due to the rupture of the rectum during spontaneous delivery and instrumental delivery and they consider it a very serious complication of pregnancy. In fact, they recommend either therapeutic abortion if recognized early or cesarean section if late.

We agree totally with Hartmann that the treatment of choice of low strictures of the rectum is excision. We further believe that as

our technique improves the mortality will become lower. It is also our opinion that surgeons in clinics who see large numbers of these cases will eventually come to this conclusion.

CASE REPORTS

The first patient was seen and operated on in private by one of us (L.T.W.) A brief abstract of her history follows.

C. M. colored female, married, 34 years of age mother of one child 12 years of age was first seen in the office in November 1924 at which time she complained of an abscess near the rectum. She was emaciated, anemic, nervous, and weak. The only other essential point in her history was that she had a history of having 7 operations for perirectal abscesses during the previous 5 years. Constipation, deformed stools and at times passage of blood and mucus from the rectum completed her history. Examination revealed a stricture of the rectum which would barely admit a No. 24 F catheter. Two fistulous openings were present on the right side of the rectum. The perineum showed perianal and perirectal thickening. In December, 1924, posterior proctotomy with wide excision of all fistulous tracts was done. In October 1925 left inguinal colostomy was performed. In January 1926, the rectum was excised preserving the external sphincter mechanism according to the method of Victor Panchet. Convalescence was slow but uneventful and complete healing of the perineal wound did not occur for a period of 2 months. This patient frankly stated that she would prefer to die rather than have a permanent artificial anus and that she would willingly undergo any risk that would offer her a chance of health. Later the colostomy was closed. In the spring of 1945 19 years after her original resection this patient reported that she was in excellent health.

This first patient, with several others was demonstrated at a symposium given in 1938 by the surgical department of our hospital in honor of Dr. Wilhelm Frel. Because of the satisfactory result in this case we were stimulated to use the method beginning in 1931 on the surgical service of Harlem Hospital, and the authors of this article constituted an in-door group for the clinical study of these cases. All of the second stage operations were performed wholly or in part by the senior author (L. T. W.).

We have used this operation in 26 cases. The following is an illustrative case referred to the senior author.

J. G. colored woman 26 years of age married 5 years, never pregnant, husband living and well.

SURGERY GYNECOLOGY AND OBSTETRICS

History of rectal bleeding, pain during defecation with a discharge of pus and mucus from the rectum during the past 4 years. She had been hospitalized on two or three occasions for dilatation of the stricture without much permanent relief. She had been having chills and fever off and on for the past 2 years. Physical examination revealed a tight annular stricture of the rectum one half inch above the anus which did not admit the tip of the little finger. The blood count showed 4,000,000 red blood cells, 86 per cent leukocytes, 74 per cent polymorphonuclears. The Frel test was strongly positive. Urinalysis showed occasional white blood cells and red blood cells. Blood chemistry creatinine 1.2 urea nitrogen 13 sugar 75 Wassermann test negative. Colostomy was performed May 11, 1936 (Fig. 3). She was discharged May 31, 1936.

She returned on October 5, 1936 for the second or excision stage of operation, which was performed on October 6. Pathological report by Dr. Solomon Weinstein: large mass of tissue 5 by 5 by 5 centimeters. The mass had an irregular nodular surface, with moderate hemorrhagic discoloration of the surface. The mass itself showed marked fatty infiltration and on cut surface had a grayish white fibrous appearance and extremely firm consistency. Microscopic diagnosis acute and chronic inflammation of the rectum with fibrosis. She was discharged on December 6, 1936. On March 1, 1937 she returned for closure of the colostomy and was discharged May 22, 1937. Figure 4 shows the condition at the time of her discharge. In reply to a letter of inquiry her referring physician wrote on December 14, 1943 as follows:

I examined Mrs. G. in 1943 for some other condition. At that time she had no gastrointestinal symptoms whatsoever. Examination showed a somewhat patulous but perfectly competent anus. At the end of the examining finger rectally there was a slight degree of nonobstructing rectal constriction. The patient weighed 35 pounds more than she did in 1936, and she felt very well.

Examination in our follow-up clinic in February 1944 was as follows: no trouble with the rectum since closure of the colostomy in 1937. She has full control of her bowels. On examination she showed a red linear scar in the suprapubic region from hysterectomy operation which she had on September 24, 1943 for fibroid uterus. The skin around the anal margin was soft, the mucosa red and healthy. There was no stricture or ulceration.

In the 26 cases, in which the above procedure was carried out, 2 deaths occurred in the hospital. One death occurred on the day of operation—the resident surgeon had failed to appreciate the fact that the patient was in secondary shock and needed a transfusion. Another patient died of peritonitis following closure of the colostomy by one of the asso-

ciate surgeons on the staff death, of course, was not attributable to the excision operation. We have been able to follow 12 patients, 7 to 19 years after operation and the result in 8 cases was satisfactory. One patient still had sinuses on each side of the rectum which intermittently drained a slight amount of pus. This patient showed osseous involvement and was reported as such (28). Another patient showed a slight tendency toward rectal prolapse where the mucosa had separated from the skin margin. One patient showed a stenosis at the anal margin. One patient became psychotic. It is of interest to note that in all of these patients, excepting the one with the draining sinuses, the disease was completely eradicated also that 8 of these patients had as excellently functioning anus with control over their bowels except when they took laxatives.

TECHNIQUE

The operation was performed in three stages in 24 of the 26 cases. The following drawings—Figures 5, 6, 7, 8, 9, 10 and 11 which are after Pauchet, and No. 12 which is diagrammatic—illustrate various steps in the operation. The first stage is the making of a temporary colostomy. After the colostomy and when the general condition of the patient has improved to the point where it is felt that she can withstand a resection, an effort is then made to disinfect the distal sigmoid and rectum in so far as possible as a preliminary to resection of the rectum. The second stage is the stage of resection and after this has healed, the third stage is to close the colostomy. The time interval between the different stages varies according to the clinical condition of the patient.

Early in our studies we used baryum enemas to determine the length and extent of the strictured area, but we soon found that its use was more a disadvantage than an advantage, the reason being that, although the procedure did give us some information as to the height of the stricture the baryum often became inspissated above the stricture and was extremely difficult to remove. We later learned to investigate the extent of the stricture when the abdomen was open while we were performing the colostomy. Before any operation is

Fig. 1. Patient C. A. Appearance on admission November 30, 1938, of an abdominoperineal resection of a stricture performed at another hospital 6 months previously on June 3, 1938. She was emaciated, weak, and dehydrated. The infection had burrowed upward along the supraspinous ligament to the level of the fifth dorsal vertebra.

Fig. 2. Patient C. A. Appearance at time of discharge March 1, 1939. The entire area of infection was opened widely and packed with zinc peroxide, which resulted in healing.

undertaken we take great pains to explain to patients that they may have to go through life with a permanent artificial anus in the event we should find at the time of the colostomy operation that the stricture extends so high that it is not resectable. Thus the patient understands thoroughly beforehand and agrees to and it is also understood that if the stricture is one that will lend itself to resection that will be done and that eventually the colostomy opening will be closed.

Two low strictures were resected in a one stage operation without colostomies having been previously performed (Figs. 13 and 14). In these 2 cases it was possible to resect the rectum without entering the peritoneal cavity and the healthy rectum was brought down intrasphincterically and sutured to the surrounding skin. The only trouble with this procedure and for that reason we gave it up is the fact that although it cures the patients of their disease and their stricture it also brings the cervix of the uterus down to the vaginal introitus, and to this condition the patients later objected strenuously.

In performing a colostomy for stricture of the rectum the sigmoid and rectum are examined carefully as to the length of the stricture, the extent of infiltration of the disease and a search is made for enlarged lymph nodes; this information is used as a basis for deciding for or against resection. In a few

cases not included in this series, the sigmoid was found to be plastered down to the posterior abdominal wall and the rectum and sigmoid exhibited thickening of their walls and luminal narrowing which rendered them

Fig. 6. Anus has been closed (its suture, and the line of incision is shown (drawing after Panchet).

obviously unsuitable for resection. In one patient, not included in this series, following resection the new anus cicatrized to such a point that we were not able to close the colostomy. This patient refused further treatment because she was satisfied with the colostomy. There is however no evidence of active disease around the rectum. In a large number of colostomies performed by us in this disease we have searched carefully for iliac and other glandular enlargement this we have never found. For anemia at first we used ventriculin with iron which helped to overcome the anemia rapidly. All of these patients gave a positive Frei reaction 20 of the 26 gave a positive Wassermann reaction.

In general these patients at the time of the preliminary colostomy were usually emaciated, toxic, and in very poor general clinical condition. They were allowed to go home until their clinical condition improved, which was 3 or more months, after which they were brought back for the second stage of the operation which was the excision of the rectum with preservation of the sphincter. After the latter stage which required usually from 4 to 8 weeks to heal the patients were allowed to go home for a few weeks, if they so desired,

Fig. 7. A Button of skin around anus. B Sphincter ani muscle exposed following dissection of anal mucous membrane. C Line of curvilinear incision (drawing after Panchet).

Fig. 8. The lower flap contains the sphincter and muscle (drawing after Pauchet)

after which they would return to have the colostomy closed. It should be pointed out that these patients because of their poor clinical condition before the colostomy and because of the magnitude of the second or excision stage require a longer period of hospitalization than do most patients and during this time they require careful supportive treatment.

The technique used was not original with us, but we followed in the main the one described by Pauchet. Preliminary to the resection stage of the operation it was our custom at first to instill thrice daily 2 ounces of a 10 per cent solution of argyrol into the distal segment so as to render it as bacteria free as possible; later we irrigated the rectum through the colostomy opening with a 1:5000 solution of zephiran. Ether anesthesia was used.

The anal sphincter is dilated fully; the anus is closed with a heavy silk suture and an area of skin about the size of a silver dollar is dissected up exposing the external sphincter

muscle. The mucous membrane lining the anal canal is freed with scissors and blunt dissection just as in the Whitehead operation for hemorrhoids. The stricture is usually located at the junction of the rectum and the internal opening of the anal canal. A curvilinear incision is made that extends from near the tuberosity of the ischium on one side upward to the fourchette and then downward to the area over the tuberosity of the ischium on the other side. The anterior wall of the rectum is then separated from the posterior wall of the vagina. At times the rectum is unavoidably opened at this point, but where this has happened no serious infection has developed.

The levator ani muscles on each side are divided between clamps close to the rectum and ligated. At this time one cuts through much scar tissue which bleeds and oozes very freely; this hemorrhage is controlled by the frequent use of hot pads. After a partial dissection of the stricture from its surrounding

Fig. 9. The pouch of Douglas has been opened (drawn after Lauchet).

tissues the apron of skin which carries in it the sphincter muscles is allowed to fall forward and downward. The firm rectococcygeal ligaments are divided and retractors hold the skin flap downward. The rectum is then easily freed in the hollow of the sacrum and its lateral fascial attachments above the levator ani muscles are divided.

The peritoneal cavity is entered through the pouch of Douglas. The rectum is pulled down to a point above the strictured area. The superior hemorrhoidal vessel and all other bleeding points are carefully ligated. The diseased portion of the rectum is excised at a point through healthy rectal tissue. The proximal end of the rectum is brought down intrasphincterically and its margins are sutured to the skin edges with interrupted black

silk sutures which bring the rectal mucous membrane in direct contact with the skin. Two Tenrose or cigarette drains are placed into the peritoneal cavity, one coming out at the lower angle of the wound on each side as shown in the illustration (Fig. 11). A piece of vaseline gauze is placed in the new anal canal.

The patient is given a blood transfusion, 500 cubic centimeters of blood immediately after the operation and she is watched very closely during the next 4 hours for the possible development of secondary shock. If the patient during this time goes into shock again another transfusion is given, usually 200 or 300 cubic centimeters of blood. During the same immediate postoperative period an intravenous drop of normal saline solution is given. The following day the patient's bed is placed in

Fig. 10. Division of the rectum proximal to the stricture (drawing after Pauchet)

high Fowler's position. After the rectal operative site is healed the colostomy is closed.

OBSERVATIONS

In performing the preliminary colostomy it is important to use the segment of sigmoid

Fig. 11. 1 Drain, which extend up into the pouch of Douglas. 2 New anal canal (drawing after Pauchet)

Fig. 12. Diagrammatic cross-section view at end of operation. A Cut edge of peritoneum. B Rectum. C Sphincter and muscle. D Suture approximating mucous membrane to skin.

Fig. 3. Patient H. F. Photograph of Introltus of patient who had a one stage resection 4 years previously. A The cervix at the opening of the vaginal canal. This patient became pregnant and was delivered by cesarean section, year after resection of the rectum. Thirteen years later this patient has a well functioning anus but her cervix is still at the introltus. In this condition she has refused to have corrected.

Fig. 14. Patient N. H. Operative site 2 years after one stage resection. No evidence of disease. Well functioning anus and rectum.

Fig. 15. Operative specimen patient C. W. age 24 years. Stricture complicated with rectovaginal fistula. First stage December 4, 1936. Second stage May 1937, at which time specimen was removed. Colostomy closed February 9, 1938.

that is at the highest point above its mobile part. This step will permit the segment to be drawn down when the rectum is resected. In one instance this point was not observed when a colostomy was performed and, during the resection stage of the operation, after the rectum was freed and the diseased portion excised, there was not sufficient mobility to permit the bringing down of the healthy end of the rectum to the skin. This patient developed a psychosis upon learning that she would have to keep her artificial anus and she was transferred to a mental institution where she died. It is imperative that the highest mobile point of the sigmoid be the site of choice for the performance of a preliminary colostomy if the structure is resectable. If the structure is not resectable the making of a colostomy at that site for a permanent artificial anus is dangerous because there may be the development, later of a retrograde herniation in a few cases.

With the advent of the sulfonamides, particularly sulfasuxadine which has been a boon in lessening infection in the large bowel, it is possible that we may be able to do these resections in one stage and open the peritoneal cavity without danger. This we have not yet attempted. We still believe that the three

Fig. 16 Patient M. B. Anal tumor, stricture of rectum, and fibroid of uterus. Colostomy and hysterectomy May 14, 1932. Resection of tumor with stricture by dividing lower third of vagina and sphincter muscles. Closure of colostomy October 8, 1932. Follow-up 12 years later showed good results.

stage operation of preliminary colostomy followed by resection when the clinical condition of the patient has improved and followed by the closing of the colostomy is the procedure which gives the patient the greatest protection.

Sometimes these patients present tumor masses around the anus which have to be excised at the time of the second operation. Figures 16 and 17 show the external appearance in 2 cases in which resection was done and the end results were excellent.

Dr. Milton J. Schreiber from the obstetrical service reports that he has delivered spontaneously 4 of the patients who have had excision operations in this series without any ill effects.

We have had no experience with Hartmann's method of perineal resection, the Lockhart Mummery method of resection as used by Edwards and Kindell and Barber and Murphy and the modification as used by Woods and Hanlon. In all of our cases we have preserved the sphincter, a point which Hartmann later conceded to be important although his operative approach was sacral rather than the approach which was used by Pauchet.

Fig. 17 Patient V. B. Anal condition at time of admission in 1934. Three stage operation. Well functioning anus in 1945 at which time she was on the gynecological service for a pelvic mass. No signs of anorectal disease.

It should be clearly understood that the operation of excision is a very serious operation and one to be used only in selected cases and by surgeons of experience. It should not be performed by the surgeon who does this type of operation only occasionally although we are certain that as a given surgeon's operative experience with the disease grows his results will improve. It is hoped that early diagnosis and the use of chemotherapy will obviate the necessity for the use of surgery in these cases before a true rectal cicatricial stenosis has occurred.

CONCLUSIONS

1. Resection of the rectum with excision of the diseased area and preservation of the sphincter is the treatment of choice in certain selected cases of fibrous stenotic strictures of the rectum.

2. Permanent colostomy may have to be performed as an operation of necessity when the disease is so extensive that it cannot be resected with ease.

3. Abdominoperineal resection may be justified in certain cases in which the stricture extends so high that a sphincter preservation operation cannot be done.

4. Twenty six cases in which resection of the rectum with preservation of the sphincter was performed according to Pauchet's technique are reported with 2 immediate deaths.

and 1 later death. These 2 immediate deaths were preventable and cannot be ascribed to the operation *per se* but to our inexperience. Follow up of 12 cases shows that the disease was cured in all but one and this one present fistulous openings which drain intermittently due to bone involvement.

5. Pauchet's operation has proved a satisfactory procedure in our hands and is worthy of further trial.

6. Two very low strictures were resected in one stage and they resulted in complete cure.

7. Early diagnosis in our opinion followed by an excision operation is the best treatment for fibrous strictures of the rectum.

LIGATION OF THE INNOMINATE ARTERY FOR INNOMINATE ANEURYSM USING RUBBER BANDS

Report of a Case

JOSHUA C. TRENT, M.D., F.A.C.S., Ann Arbor, Michigan

OF the fewer than 100 operations performed on the innominate artery since Valentine Mott's initial report in 1818, approximately 25 per cent have been for innominate aneurysm. Greenough in 1929 collected from the literature 91 ligations or attempted ligations of the innominate artery; only 17 were performed for aneurysm of this vessel and in only 13 was the artery actually tied. In 1937 Rundle added 8 cases to Greenough's 13 (3 of these Greenough had listed as subclavian aneurysm)¹ and Brock in 1941 added another. From these reports and including the present case it appears that the innominate artery has been ligated some 23 times for aneurysm.

The relative infrequency of ligation of the innominate artery for aneurysm is understandable because of (1) the rarity of the condition (innominate aneurysm accounts for less than 3 per cent of the total), and (2) the high mortality of the operation (Table I). A successful case was not reported until 1911 by Sargent although Cunco according to Guinard successfully ligated the innominate artery for aneurysm in 1905. Many more successful ligations have been performed during the past 25 years but the procedure remains hazardous with secondary hemorrhage still the chief cause of death (Table II).

Greenough gives a detailed description and analysis of the types of operations employed on the innominate artery including proximal or distal ligation or both, ligation of the innominate and subclavian or carotid vessels, triple ligation of the innominate, subclavian and carotid arteries, triple ligation and excision of the sac and innominate, carotid and

TABLE I—MORTALITY IN 28 CASES OF OPERATION ON THE INNOMINATE ARTERY FOR INNOMINATE ANEURYSM

	Ligation	Mortality	Attempted ligation	Mortality

vertebral ligation in which silk, hemp, ox aorta, ox peritoneum, kangaroo tendon, catgut, catgut chromic, catgut, horsehair, silver wire and many other materials were used as ligatures. He concludes that multiple ligation is advisable, combinations including the subclavian surpass those with the carotid and the vertebral should not be included.

After careful evaluation of the operative treatment of innominate aneurysm, Rundle reaches similar conclusions: (1) if an attempt is to be made to ligate the innominate trunk, it is essential to split the sternum; otherwise access is inadequate and the ligature may fail to occlude its lumen; (2) simple proximal ligation as a method of treatment is most unsuitable while necessitating as thorough an exposure as the more complete operation; it gives the poorest results and is too prone to be followed by cerebral vascular complications.

In any type of ligation of the innominate trunk, there are two circulations to consider:

From the Department of Surgery, Duke University Hospital, Durham, North Carolina.

Early reports of ligation of the innominate artery for aneurysm are frequently difficult to interpret because of the failure of the authors to describe the exact location of the lesion.

Fig. Anterior and lateral views of the patient 10 days after operation. The operative scar is clearly visible. The aneurysmal mass no longer pulsates but is approximately the same size as on admission.

the peripheral and the cerebral. Greenough in 75 ligations found no cases of gangrene of the homolateral arm although there were several cases of atrophy. There were 7 deaths from cerebral lesions, some of which must be attributed to ischemia.

Although the recommendations for surgical therapy outlined above are sound they are not always applicable, a fact well illustrated by the following case which presents several unusual features, namely (1) the approach to the innominate artery was through the chest rather than the sternum since it was feared that manipulation of the sternum or clavicle would result in the tearing of the wall of the aneurysm, (2) rubber bands were used to ligate the vessel, and (3) the aneurysm completely disappeared following proximal ligation of the innominate trunk.

CASE REPORT

R. W. A. 51137, 51 year old colored male, was first seen at the Duke Hospital November 11, 1940. At that time he had a strongly positive blood serology and spinal fluid. A diagnosis of central nervous

system syphilis was made and the patient referred to the local Department of Public Health where he received a course of antilimetic therapy.

He returned to the clinic May 31, 1944, stating that 1 month prior to his visit a small knot the size of a walnut had appeared suddenly at the base of his neck on the right after a severe coughing spell. The cough had continued and the "knot" had grown rapidly in size. He had no obstruction to his breathing but had noticed some hoarseness and dysphagia. He complained also of throbbing headaches which seemed to be synchronous with his heart beat.

Physical examination revealed fixed pupils, a blood pressure of 148/110 in the right arm and 14/100 in the left, a heart slightly enlarged to the left with an irregular rhythm due to dropped beats, and a late diastolic murmur over the aortic area. Just above the clavicle and resting on it was a large pulsating definitely expansile mass measuring approximately 10 by 12 by 7 centimeters (Fig. 1). The mass extended beyond the midline although it was predominantly on the right. The trachea was markedly deviated to the left and laryngoscopic examination was unsuccessful. The size of the aneurysm prohibited ante flexion of the head.

Röntgenograms of the chest (Fig. 2) showed slight enlargement of the heart to the left with some tortuosity of the aorta but no definite aneurysm of this vessel. A shadow in right supra cardiac region

Fig 2 a, Preoperative roentgenogram of the chest showing the shadow in the right suprasternal area characteristic of an enlarged innominate artery. Slight enlargement of the heart to the left and tortuosity of the aorta but no definite

inite aneurysm of this vessel. The trachea may be seen far to the left. b Seventeenth postoperative day. Roentgenogram of the chest showing the elevated diaphragm on the right.

was characteristic of an enlarged innominate artery. The trachea was displaced considerably to the left.

A diagnosis of aneurysm of the innominate artery and possibly the right common carotid artery was made and the patient referred to the surgical clinic for consideration of ligation of the innominate artery.

He was admitted to the surgical service on June 16, 1944, stating that the mass in his neck had increased in size since his last visit to the clinic. The physical findings were essentially unchanged over those last recorded except for a slight increase in the size of the aneurysm.

The accessory clinical findings were as follows: hemoglobin 13.4 grams (86%), red blood count 4,160,000, white blood count 6,360, blood Wassermann reaction positive, Kahn positive, Kline and Mazzini tests negative. Spinal fluid tests showed Wassermann reaction 00000, colloidal mastix test 0000000, Pandy negative, cell count 0.

Fluoroscopy and films of the chest showed the changes described. The electrocardiographic record was indicative of coronary artery disease.

A diagnosis was made of syphilitic aneurysm of the innominate artery, syphilitic cardiovascular disease with cardiac enlargement and myocardial damage from coronary involvement, aortitis and dilatation of the aorta.

During the 9 days the patient remained in the hospital before operation the aneurysm increased visibly in size, and rupture appeared imminent.

Therefore, in spite of electrocardiographic evidence of coronary involvement and the attendant high operative mortality, ligation was recommended. A week before operation patient was given 2 cubic centimeters of bismuth subsalicylate intramuscularly.

On June 24, 1944, with the patient supine and under pentothal and endotracheal 50 per cent nitrous oxide-oxygen anesthesia, a hockey-stick incision was made over the second rib anteriorly on the right extending vertically along the lateral border of the manubrium to the jugular notch. The underlying pectoral muscles were cut and the second rib exposed and resected as far laterally as possible. The costal cartilage was rongueured away to the sternum; care was taken not to injure the mammary vessels. The pleural cavity was entered through the rib bed. In order to obtain better exposure the third rib was divided laterally and medially. The under surface of the aneurysm could be visualized readily and palpated at the apex of the pleural cavity. The pleura overlying the great vessels was divided and reflected back. The innominate veins and the superior vena cava were separated from the underlying arch of the aorta and the innominate artery and retracted, exposing the greatly dilated innominate trunk which measured approximately 4 centimeters in diameter at its junction with the aorta. By careful manipulation and dissection a large goose-neck clamp was passed under the vessel and a cotton tape placed around the artery (Fig 3). It was feared

Fig. 3. The right chest was entered through a hockey stick incision over the second rib (left upper inset). The pleura overlying the great vessels was incised, the fat pushed back, the veins retracted, and the innominate artery exposed. A goose-necked clamp was passed behind the artery and two rubber bands pulled through by means of a tape (central cut). The rubber bands were stretched and sutured anteriorly using heavy braided silk (left lower inset). The ends were trimmed and the protruding bulb covered with muscle (right lower inset).

that secondary hemorrhage might follow ligation of such a large thin walled vessel with a narrow non elastic ligature. Therefore two new rubber bands 2 millimeters in width and 7.5 centimeters in length were obtained sutured to the tape and drawn under the vessel. The bands were then pulled up very snugly around the vessel and sutured together anteriorly using a heavy braided silk figure of-eight suture. After the lumen of the vessel had been thus occluded there was immediate cessation of pulsation in the aneurysm and right superficial temporal artery and the blood pressure and pulse in the right arm could no longer be obtained. After the rubber bands had been trimmed, a small nubbins remained which lay immediately beneath the innominate veins, and the possibility of erosion into these vessels had to be considered. To obviate this, a piece of muscle was sutured over the stiff protruding ends, to form a soft pad between the ligature and

vessels. The wound was then closed in anatomical layers, with continuous chromic or Dorex suture for the pleura, interrupted double medium cotton for the muscle and fascia and interrupted fine cotton for subcutaneous tissue and skin. Patient stood operation well and returned to ward in good condition.

Following the operation no weakness of the homolateral arm or opposite side was noted. He had a fairly stormy course for the first 3 days due to the development of bronchopneumonia, but on the fourth day following penicillin and sulfadiazine therapy his temperature returned to normal. On the fifteenth day small tender fluctuant areas developed over the crest of the aneurysm. The aneurysm no longer pulsated but had not decreased appreciably in size. Aspiration of the fluctuant areas yielded pus and blood which contained gram positive cocci. To forestall spontaneous rupture, a small incision was made in the skin at the point of aspira-

Fig. 4 Three weeks postoperative. Anterior and lateral views of the patient showing almost complete disappearance of the mass. The opening of the small draining sinus can be seen just above and to the right of the jugular notch

Fig. 5 Six weeks postoperative. Anterior and lateral photographs show a further decrease in the size of the mass. The opening of the supraclavicular sinus tract is evident.

Fig. 6 a, Roentgenogram of the chest made approximately 3½ months postoperatively showing prominent shadow over the right apex displacing the aortic arch.

the left. b, Roentgenogram of the chest made 3½ months after operation showing clearing of the right apex with residual mass in the region of the bronchial artery.

Fig. 7 Ten months postoperative. The mass has completely disappeared and the sinus tracts have healed. The outline of the right sternomastoid muscle is clearly visible. Subjectively the patient is well.

Fig. 8. a, Ten months postoperative. There is a large dense mass in the right supraclavicular area at the site of the ligation. The trachea is practically in the midline. The

diaphragm has descended. b, A kymogram made of the chest reveals no pulsation of the mass which has been described in a.

tion and 100 cubic centimeters of pus, old blood and thrombus were expressed from the neck. No hemorrhage ensued. Following this, the mass in the neck disappeared (Fig. 4). Compresses were applied, the inflammation and induration subsided and healing occurred except for a small persistent sinus. A chest plate on the seventeenth day showed the chest to be clear with the trachea still slightly deviated to the left. The right diaphragm was elevated and fixed from stretching of the phrenic nerve at operation (Fig. 5b). A slight pulse was felt in the right arm on the seventeenth day but the blood pressure could not be recorded. The blood pressure in the left arm was 118/76. Oscillometer studies of the right arm revealed a maximum of 2 units pulsation above the elbow. An electroencephalogram showed no depression of cerebral activity on the right. He was discharged on the twenty first day with instructions to continue his antitubercular therapy.

On August 7, 1944, the patient was readmitted to the hospital complaining of bleeding from the site at which the infected aneurysm had been drained (Fig. 5). Physical examination and chest findings were essentially as on discharge July 14, 1944.

While in the hospital fairly brisk bleeding occurred from the sinus with an estimated blood loss of 500 to 700 cubic centimeters. He was given a blood transfusion. A skioldan injection of the sinus tract revealed only a small pocket at the site of the aneurysm. It was felt that the hemorrhage probably had come from the vessels communicating with the old

aneurysmal sac. An attempt was made to thrombose these vessels by injecting first a solution of 50 per cent glucose and later 5 per cent sodium morrhuate into the tract. Following this no further hemorrhage occurred. The cavity decreased in size and the patient was discharged on August 22, 1944.

On August 26, 1944, the patient was readmitted complaining of a swelling under the old thoracotomy wound which later proved to be an abscess. It was feared at first, however, that it might be due to further hemorrhage and since he was afebrile it was not incised. He was discharged on August 27, 1944.

On September 4, 1944, the patient was readmitted complaining of increase in the size of the swelling under the old incision and further bleeding from the supraclavicular sinus tract. He had some fever and since there was some clouding of the right upper chest on x-ray examination (Fig. 6a) it was decided to explore the mass. On September 7, 1944, the old thoracotomy wound was reopened and a large abscess cavity approximately 8 centimeters in diameter over the apex of the right lung was encountered and drained. The cavity contained a large quantity of thick pus from which nonhemolytic *Staphylococcus aureus* was cultured. The site at which the ligation had been done could not be visualized but it was possible that a small sinus at the bottom of the cavity communicated with it. The patient was discharged improved on September 11, 1944.

On September 28, 1944, the patient was readmitted complaining of dyspnea, substernal oppres-

swon and increasing hoarseness but no further bleeding. Re-examination of the chest by x-ray revealed that the shadow in the right upper chest was still prominent with displacement of the aortic arch to the left. It was felt that there might be a further accumulation of pus over the apex and on September 30, 1944 the old wound was again explored. No pus was found. The patient improved and was discharged on November 3, 1944.

On December 13, 1944 the patient was readmitted complaining of sudden onset of severe coughing which had persisted for 12 to 18 hours. He had coughed up 2 cupfuls of blood and had noticed some bleeding from the empyema drainage wound. Bronchoscopic examination was refused.

Physical and x-ray examinations (Fig. 6b) revealed some clearing at the right apex. While in the hospital he coughed up only a small amount of blood tinged sputum. The exact source of his bleeding was unknown. He was reassured and discharged on December 15, 1944.

On December 22, 1944 he returned to the clinic complaining of coughing up blood. His condition was good and his cough had stopped. He was reassured and sent home.

On January 31, 1945 he was again seen in the outpatient clinic with similar complaints. All draining sinuses had healed. He was reassured and discharged.

On February 12, 1945 he returned to the outpatient clinic stating that he had gotten along well except that he had coughed up a large quantity of blood on 1 occasion. General condition the same.

On April 25, 1945 exactly 10 months after proximal ligation of the innominate artery the patient returned to the clinic for a check-up. He had been receiving weekly intramuscular injections of bi-muth subnitrate since January 3, 1945. He had no dyspnea but occasionally coughed up blood tinged sputum. He had no complaints other than dizziness on leaning his head. He had excellent use of right arm but stated that in cold weather right hand became cold and stiff. Left hand not affected.

On examination the aneurysmal mass had completely disappeared (Fig. 7). The small sinus in this area and the old thoracotomy wound had completely healed. The anterior border of the right sternocleidomastoid muscle was again clearly visible. The upper mediastinum was slightly widened to percussion on the right. The lungs were clear to auscultation. Pulsation in the right brachial and radial arteries were faintly perceptible. Pulsations in the right common carotid and superficial temporal arteries were questionably felt. The blood pressure in the right arm could be heard faintly at 74/60 and 104/74 in the left. Examination of the chest by fluoroscopy and lymphography (Fig. 8a, b) revealed a large nonpulsating mass in the supracardiac area at the site of the ligation of the innominate artery. This mass was interpreted as scar tissue and not as an aneurysmal dilatation. The trachea had almost returned to the midline and the diaphragm had descended and had regained 50 per cent of its motion.

SUMMARY AND CONCLUSION

A case of syphilitic aneurysm of the innominate and common carotid arteries which first appeared after a severe coughing spell has been presented. The aneurysm was ligated proximally at its juncture with the aorta, by the use of two wide rubber bands. Pulsations ceased immediately following ligation although no appreciable decrease in the size of the mass was noted. No weakness of the homolateral arm or opposite side was observed. On the fifteenth postoperative day the aneurysm became fluctuant and was drained to avoid spontaneous rupture. Approximately 100 cubic centimeters of pus and thrombus were obtained without hemorrhage. Following drainage the mass subsided. Two and one-half months later hemorrhage occurred from a persistent sinus tract at the former site of drainage. An attempt was made to thrombose the feeding vessels by the injection of 50 per cent dextrose and 5 per cent sodium morrhuate solutions. Although these measures appeared to be effective in stopping the hemorrhage other complications developed. He returned 1 month later with an infection under the old thoracotomy wound which subsided following drainage. Subsequently both the persistent supraclavicular sinus and thoracotomy wound healed with complete disappearance of the aneurysm. There remains a residual nonpulsating mass at the site of ligation which is believed to be scarring resulting from the irritation of the rubber ligature. Patient has occasional episodes of coughing productive of blood tinged sputum due perhaps to some involvement of the trachea in the cicatricial mass. Except for these episodes the patient states that he feels as well as he ever has.

Proximal ligation of a syphilitic aneurysm of the innominate artery with rubber bands has resulted in complete disappearance of the aneurysm and clinical cure of the patient.

FAILURE OF THE UROGENITAL UNION

ALEC W. BADENOCH M.A. M.D., Ch.M., F.R.C.S., Wing Commander R.A.F.V.R.
London, England

In a fairly extensive search of the literature very little reference is found to a failure of union between the vasa efferentia of the testis and the epididymis. Hobday mentions that in the horse the epididymis is occasionally found in the inguinal canal while the testicle is in the abdomen. Kaufman (1922) and Windholz (1926) mention complete separation of the epididymis and testis, and Brunzema (1929) found this condition four times in 104 cases of undescended testis. Wilson (1939) records one case in which the testis was in the inguinal canal and the epididymis was in the scrotum. Ombrédanne (1933) describes the separation as occurring occasionally when there is a vestigial testis and Wangersteen (1932) quotes a case of an epididymis with a vestigial structure attached to it which had none of the appearance of a testicle.

UROGENITAL UNION

In a 21 millimeter embryo (7th to 8th week) the wolffian body consists of about 26 tubules situated in the lumbar region and all in a process of degeneration. This remnant of the mesonephros is divided into two portions—upper and lower. The upper or epigenital part consists of 5 to 12 tubules the blind ends of which become surrounded by the epithelial nucleus, forming in the indifferent reproductive gland so that each comes to be in a sort of bay in that part of the nucleus from which the rete testis is formed. From the beginning therefore the wolffian collecting tubules and the tubules of the testicular rete are in intimate contact and lie wall to wall. The urogenital union takes place when the two open into each other (Fig. 1) and this appears to occur at very different periods. Felix saw it first in a 60 millimeter embryo—head foot length.

When union has taken place the collecting tubules are known as the vasa efferentia. In the 4th to 5th month they begin to coil at the end nearer the wolffian duct but remain

straight toward the testis. Later, they are surrounded by a firm connective tissue membrane and become the conus vasculosi. All of the 5 to 12 tubules do not necessarily take part in the union but if not, they frequently persist as remnants in the epididymis forming the vasa aberrantia. One or two may unite before joining the rete testis.

The lower or paragenital portion of the wolffian body consists of two or three small tubules closed at both ends and persists as the paradiidymis.

FAILURE OF UNION

In a series of 42 cases in which patients with incomplete descent of the testis, were operated upon I have seen 3 in which there was no macroscopical union of the testis and epididymis. In 2 of these the absence of union was confirmed microscopically.

CASE 1 A wireless air-gunner complained of pain in the right groin since beginning to wear parachute harness. On examination the right compartment of the scrotum was empty and he stated that the testis had never been down. The right testicle could be felt in the inguinal canal and pressure over it caused the pain of which he complained. The left testicle was well down in the scrotum and it and the epididymis felt normal. No evidence of hernia was noted. October 13, 1941, under nitrous oxide gas, oxygen and ether anesthesia, pentothal induction, the right inguinal canal was opened and the testis the right lying in a patent funicular process, the fundus of which reached to the external ring. When the sac was opened the testis was seen lying on the floor about 1 inch from the internal abdominal ring (Fig. 2). The sac was freed from the floor of the inguinal canal, and the epididymis was found with the globus major almost at the fundus of the process and completely separated from the body of the testis. The vessels of the spermatic cord were very short and the testis, epididymis, and sac were removed. On microscopic examination the testis showed the usual picture of an undescended organ. The seminiferous tubules were composed of a single layer of cells, occasional spermatogonia were present but no spermatozoa. There was no microscopic connection between the body of the testis and the epididymis although there appeared to be one or two ducts leading from the upper pole of the testis. The termination of these ducts were not identified.

Fig. 1. A diagrammatic representation of the urogenital union. (After Keith.)

CASE 2. Attended complaining of occasional swelling, with pain in the right groin for some 12 months. The right testicle had never been in the scrotum. A small oblique right inguinal hernia reaching to the external ring was found the right testicle was not felt. The left testicle was well down in the scrotum and it and the epididymis appeared normal. On May 2, 1912 under nitrous oxide gas oxygen and ether anesthesia pentothal induction, the right inguinal canal was opened. A small patent processus vaginalis was found. The testis was intra-abdominal but the base of the mesorchium was just inside the inguinal canal (Fig. 3) and the testis could be brought into the canal. His attacks of pain may have been due to intermittent prolapse of the testis and strangulation of the cord. The vas ran down the canal on the posterior wall of the sac and terminated in a splayed-out epididymis which had no connection with the body of the testis. The vas and epididymis could be brought well down, to reach the bottom of the scrotum, without difficulty but the testis could not on account of the shortness of the vessels of the spermatic cord. The testis, epididymis and sac were removed. Microscopically the picture was similar to that in Case 1.

Fig. 2. Failure of descent of the right testis and failure of union with the epididymis.

CASE 3. Attended with a large left sided scrotal hernia which had gradually been increasing over a period of 10 years. The hernia was easily reducible but no testicle was felt after reduction. There was a suggestion of a thickened structure, in the posterior wall of the sac, in the empty scrotum, and a pre-operative diagnosis of atrophy of the testis was made. On December 7, 1912 under nitrous oxide gas, oxygen and ether anesthesia, pentothal induction, the left inguinal canal was opened. A large patent funicular process was found. When the sac was opened, the testis was seen lying on the floor (Fig. 4) half an inch from the inguinal ring, and bonded to the sac by adhesions. The vas passed down to the scrotum and terminated in a splayed-out epididymis. This had no macroscopic connection with the testis. The funicular process was divided proximal to the latter and cleared from the cord and epididymis. The testis was then easily mobilized and brought into the right scrotal compartment. The floor of the canal was repaired with a strip of fascia.

Fig. 3. An intra-abdominal right testis and failure of union with the epididymis.

Fig. 4. Failure of descent of the left testis and failure of union with the epididymis which is well down in the scrotum. taken from the aponeurosis of the external oblique

Fig. 5. A single cyst in the mediastinum testis.

These 3 cases would undoubtedly appear to illustrate failure of the urogenital union. During the past 3 years I have almost invariably included an examination of the testis on each male patient who has been referred to me. I have not observed anything which would suggest complete failure of union in a normally descended testis and it is probable that this occurs only in association with incomplete descent. However I have been struck by the comparative frequency of the occurrence in young adults, of a small cyst in the region of the mediastinum testis, and believe that not infrequently this is due to a partial failure of the urogenital union.

Ogier Ward (1922) reported 17 cases of spermatocele and described the etiology. The youngest of these patients was 41 years and the average age was 55 years. He considers it as a disease of maturity and that a spermatocele is a retention cyst of unknown pathology. Dorne (1926) reviews the literature on the subject and also considers that the condition is a retention cyst. Among the etiological factors, he mentions trauma, gonorrhoea, or any previous inflammatory process. Rolnick (1928) in the routine examination of 55,000 men for spermatocele found a clinical incidence of 1 per cent. He operated on 12 patients and found that it was possible to dissect out the cyst in only one case which was shown to have been formed from a distended tubule. He attempted to produce true spermatocele

in 28 dogs and failed in each case. McCrea (1935) gives the following classification of cysts in relation to the epididymis: (a) cystic disease of the epididymis; (b) cysts developing between the testis and the head of the epididymis; (c) cysts of vestigial structures near to or attached to the epididymis. His view is that (a) and (b) arise from obstruction but that obstruction does not necessarily result in cyst formation. He quotes Kocher and Moc-nod and Terrillon as having described dilatation of the ductuli efferentes and considers this to be the cause of or a later step in, the dilatation of the epididymis. He considers multiple cysts to be more common and more common in the epididymis than anywhere else. He also considers that (a) and (b) are retention cysts resulting from obstruction.

In the past 3 years I have seen some 12 cases of single cyst formation in the region of the mediastinum testis occurring in men under the age of 25 years. A colleague aged 43, has had one since puberty. The large majority of patients were quite unaware of any abnormality and in most cases no comment was made on it. (It is rather extraordinary how many cases of large scrotal hernia of which the patient is quite unaware are discovered at routine medical examination.) These cysts vary in size from that of a pea to a hazel nut. They give rise to no symptoms or disability and therefore the opportunity for surgical intervention—certainly in the Service—is rare. In those that have been aspirated the fluid has contained scanty spermatozoa.

I believe that these cysts form where there has been a partial failure of the urogenital union just after the commencement of spermatogenesis.

CASE 4. Presented himself with a left inguinal hernia. On examination a cystic swelling the size of a small nut was found in the region of the mediastinum of the right testis. Aged 23 he was unaware of this and therefore had no idea as to how long it had been present. At operation after the hernia had been repaired an incision was made in the right scrotum and the cyst was found lying against the epididymis, deep to the tunica vaginalis (Fig. 5). It was rather pear-shaped with the narrow or tail-end toward the testis. In the cyst fluid were scanty faintly motile spermatozoa. The cyst appeared to be a distended vas efferens.

I have noticed that occasionally after epididymectomy a cystic swelling forms in the region of the mediastinum testis. It makes its appearance within a few weeks of the operation and may grow to the size of a hazel nut. In 2 such cases in the last 18 months scanty spermatozoa were found in aspirated fluid. After aspiration the cyst refilled within a few days. It has all the characteristics of a spermatocele and has occurred when there is a complete absence of union between the testis and the collecting system.

SUMMARY AND CONCLUSION

Failure of the urogenital union has received only scanty attention in medical literature and very few cases have been described. Three cases of complete failure of union occurring in a series of 42 adults operated upon with incomplete descent of the testis are now reported. It is thought that complete failure of union occurs only in association with undescended testis. Incomplete failure of union is put forward as a suggested cause for the occurrence of single mediastinal cysts in young adults.

PRELIMINARY REPORT OF A METHOD FOR THE PREVENTION OF LEAKAGE OF INTESTINAL ANASTOMOSES

An Experimental Study

JOHN DEVINE, M.S. (Melb.) F.R.A.C.S. Melbourne Australia

THE methods herein described were evolved for colon anastomoses but are applicable to all other gastrointestinal anastomoses, including small bowel anastomoses, gastroenterostomies and closure of the duodenal stump.

It was noticed both in the postmortem department and in instances in which experimental sutures had been put into redundant exteriorized colon (when it was brought out of the abdominal wall after the operation of excision of the rectum) that each particular suture hole became infected and therefore a potential source of sepsis or leak age. Thus sutured anastomosis of the colon must always have an element of risk, and although with the bringing of peritoneum to peritoneum with silk sutures which traverse only peritoneum (where this is present) the risk is minimized its dangers in any but the most experienced hands has led in many cases, to the adoption of Paul Mikulicz procedures followed by nonsuture anastomosis with a crushing clamp aseptic anastomosis techniques, and many other methods. It has been long recognized that the most important sutures are those that bring peritoneum to peritoneum and in some methods of aseptic anastomosis no attempt is made at mucosal apposition by suture. Another method of nonsuture anastomosis is the Murphy button. This method gave safe anastomoses of the small bowel with peritoneum to peritoneum junction without sutures (where the bowel is covered by peritoneum) although the button is seldom used these days. Anastomoses in parts of the bowel not completely invested by peritoneum are most difficult to accomplish successfully by any method.

The problem of suturing the large intestine can be considered to be comparable to suturing the inner tube of a motor tire. Here sutures cannot be employed to repair rents because each stitch put into the rubber tube would leak air therefore punctures in tires are mended by "vulcanizing on patches over the holes."

The method herein described involves the "vulcanizing on" of peritoneal grafts or split skin

From the Physiological Department, University of Melbourne.

grafts over the suture line, whether or not the surface is covered by peritoneum. It is a procedure supplemental to the usual methods of anastomosis. It takes very little more time and there is nothing to lose if it fails.

METHOD EMPLOYED

In 1943 Sano reported a method of 'sticking' on skin grafts using dried plasma and leucocyte cream the graft was placed in contact with the recipient area without sutures. Adhesion occurred in a few minutes. In 48 hours the graft had a blood supply and was completely fixed in 4 days. Young and Favata in 1944 further simplified this procedure using thrombin solution on the unwashed skin graft, and normal pooled plasma on the recipient area. This method has been used successfully by the author in applying skin grafts cut with the dermatome, thus avoiding the necessity of suturing the graft in position and of applying pressure. Further work by Cannady (1943) had shown that strips of skin were useful in repairing a hernia and that no harm came from dermis in the tissues.

An experimental study was therefore undertaken to see whether skin or peritoneum could be grafted over the suture line of colon anastomoses on the assumption that any method which would be successful in the colon would be at least equally successful in the small bowel and stomach. The method of fibrin fixation of a graft to bowel would be physiologically sound as after all the normal formation of intra abdominal adhesions must occur by that method. Fibrin fixation of skin grafts was an established fact and had been personally found useful. However it remained to be seen whether peritoneum would 'receive' peritoneal grafts whether intracolonic pressure would 'blow off' grafts whether soiling and consequent sepsis would prevent the graft from 'taking' and whether such a convenient strong grafting material as skin or split skin could be used in the peritoneal cavity.

EXPERIMENTAL PROCEDURES

Dogs were used in the experiments because they have a strongly mobile small colon which

Fig. 1. Experiment 1. Showing most of free omental graft still sticking to the suture line.

makes surgical procedures difficult and are susceptible to general peritonitis; therefore, it followed, that they were suitable for testing the efficacy of the graft. Ten small dogs were used

TABLE I — PROTOCOL

Group A. No pressure of any kind applied.

Experiment	Type of graft	Result	State of graft	Sealing of peritoneum
	Free omental	Death 4 hrs	Half graft adherent	+++
	1/2 graft on suture line (peritoneal graft stuck well on gut)	Death 24 hrs		++++
	Peritoneum	Death 4 hrs	Adherent except at mesenteric border	++
5	Whole thickness skin	Death 30 hrs	Well adherent except at mesenteric border	+

Group B. Free peritoneal grafts held in position for about 5 minutes with pressure

	Peritoneum	Alive (killed 6th day)	Adherent	Nil
7	Peritoneum	Alive (killed 6th day)	Adherent	Nil
8	Peritoneum with hole in it	Death 7 hrs	Graft fully adherent; leak had occurred through the hole	++
	Peritoneum	Death 48 hrs	Adherent	Nil
	Peritoneum	Alive (killed 6th day)	Adherent	Nil

Group C. Exteriorized colon.

Whole thickness skin and peritoneum	Both adherent and remained adherent
-------------------------------------	-------------------------------------

Fig. 2. Experiment 2. Showing omentum stuck to peritoneal graft which was also firmly stuck in position.

In the first 6 differing trial techniques were used, and in the succeeding 4 at a later date a more or less standardized technique was followed. In all cases the ascending colon was cut across between rubber bowel clamps to stop undue fecal contamination, and then the ends were joined together by a single continuous through-and-through silk suture which went through all bowel wall layers at once and encircled the bowel and was tied only when it came back to the place from which it started. This admittedly inadequate method of anastomosis was not assisted by the use of either a Miller Abbott tube or an artificial anus to take tension off the suture line. In some cases feces could be observed to issue from the ineffective suture line immediately after the removal of the clamps, and in the control experiment in which this suture was used alone, death occurred within 24 hours, and it was found that the abdominal cavity was full of feces. It will thus be seen that the greatest possible strain was thrown on the grafts in testing their efficacy in the prevention of leakage of intestinal contents.

RESULTS

In the first 6 experiments various procedures were used, but in only 1 case (Table I) was the graft applied with pressure. This dog lived and was killed at the end of a week, when the graft was found sticking firmly in position without any sign of leakage or peritonitis. (In the dog in which no graft of any sort was used, death occurred within 24 hours with feces being widespread throughout the peritoneal cavity.) In the remainder in which whole thickness skin, peritoneum and omental grafts were used, all were found to be firmly stuck on to the anastomosis despite the fact that pressure during application had

Fig 3 Experiment 5 Showing skin adherent to suture line

not been used but in these cases (with 'no pressure' technique) leakage had occurred at one spot or another usually at the mesenteric border

In the second series of 4 cases, peritoneal grafts only were applied with pressure for about 5 minutes. No sutures of any sort were used to fix or to hold the grafts in position in these 4 cases. 2 were alive and perfectly well at the end of 6 days, and when they were killed no peritonitis was found. In each of these cases the graft was strongly fixed in position. In one other case death occurred in 48 hours from a general hemorrhage through out the peritoneal cavity no peritonitis being present and no bowel leakage having occurred and the graft was still firmly fixed in position. The fourth died after 72 hours with general peritonitis. The graft in this dog was accidentally perforated in cutting but it was applied with the hole over the suture line just to see what would happen. This graft was stuck firmly in position and could not be pulled off the bowel but feces leaked through the hole in the graft (Fig 5).

Thus all 5 peritoneal grafts which had been applied with pressure stuck firmly in position and of these 2 dogs died 1 from hemorrhage and 1 from leakage through a hole in the peritoneal graft made while it was being taken (Fig 5). Of the 9 cases in which grafts were applied all grafts were found adherent at least in part. In the experiment in which no graft had been applied to the suture line a peritoneal graft applied to the colon elsewhere was firmly adherent.

The application of these findings to the human was first done on exteriorized redundant bowel left outside the abdominal cavity after the operation for excision of the rectum. A graft of whole thickness skin and a graft of peritoneum were both taken at the time of operation and refrigerated for 6 hours before application to the exteriorized

Fig 4 Experiment 7 Showing peritoneal graft stuck firmly in position.

colon on its peritoneal aspect, plasma being applied to the bowel and a few drops of thrombin solution to the graft. Pressure was applied for 4 minutes and the graft adhered readily. They were firmly fixed in 24 hours and by the third day appeared to have a blood supply and by the fourth day the edges could not be lifted. The fixation was easier than with dog plasma because human plasma is much more sticky than dog plasma and of course human bowel and skin and peritoneum are much larger and easier to handle than are the filmy dog peritoneum and small dog colon which had presented many technical difficulties in the spreading of the graft.

Fig 5 Experiment 8 Showing edematous peritoneal graft stuck firmly in position with arrow pointing to hole in the graft through which soiling of the peritoneal cavity had occurred.

Fig. 6. Experiment 6. Showing mass of omentum adhering to peritoneal graft which was firmly fixed in position.

Observation of the grafts in the dogs and man shows that they adhere with a reasonable tenacity immediately that by 48 hours they are quite firmly adherent and that at the end of a week they could not be pulled off. After 48 hours the grafts appeared to be edematous and to stay so for some days.

It is reasonable to suggest, therefore, that the employment of these grafts in intestinal anastomoses in man will be of great value and may obviate the use of staged operations now commonly performed in order to avoid the risk of leakage from the suture line.

PROTOCOL OF EXPERIMENTS

In all cases a right upper paramedian abdominal incision was made and the ascending colon cut across about 4 inches from the cecum. The ends were then joined together with a continuous silk

Fig. 8. Clamps used by author.

Fig. 7. Human. Peritoneal and skin grafts applied to exteriorized human bow. 1. A points to the skin and B to the peritoneum. (Photograph taken on fourth day.)

suture starting on the mesenteric border and traversing all coats and being tied again on return to the mesenteric border. Chloroform anesthesia was used throughout. The first 6 experiments were done on August 26, 1945 and the second 4 on September 7, 1945. Small dogs were used.

Graft A

Experiment 1. A free graft cut from the greater omentum was swabbed with a large amount of thrombi solution made by dissolving 5000 units of 5 cubic centimeters of saline. The suture line was flushed with dog plasma (collected) taken from a single dog 5 days before. The graft was laid over the bowel and a few sutures of silk fixed it to the bowel. Death occurred in about 24 hours with generalized peritonitis, and only half of the graft was found to be still adherent to the suture line.

Experiment 2. A strip from the anterior peritoneum about half an inch wide was wrapped round the bowel and moistened with little thrombi solution and the suture line was swabbed with plasma. The strip was held in position over the suture line by a firm metal clamp which compressed the bowel so that it became flat. The clamp was removed after 5 minutes, and the graft as found to be well stuck to the flat bowel. Time of death—this dog, as all, and well and was killed by chloroform on the next day when no peritonitis was found, and the graft could not be pulled off. Omentum had also stuck to one side of the neighborhood of the anastomosis.

Experiment 3. A graft of thrombi as used in postage-stamp size of peritoneum was cut and applied to the cecum after having been swabbed with thrombi and the cecum with plasma. It stuck on well and as found to be still stuck on after death. Time of death—at 24 hours. At postmortem the peritoneal cavity was found to be free of feces.

Experiment 4. A strip of anterior peritoneum about half an inch wide was banded around the anastomosis. The graft was first dried and then just moistened with thrombi. Plenty of plasma was put on the bowel itself, but no

pressure was applied. *Time of death*—at about 18 hours. A generalized peritonitic reaction and soiling of the peritoneal cavity were present, and there was a leakage from the mesenteric border where the graft was not stuck on. For the remaining circumference of the bowel the graft was firmly stuck on.

Experiment 5. A strip of whole thickness skin about half an inch wide was moistened with a few drops of thrombin and applied like a bandage round the bowel. The ends did not meet very nicely round the mesenteric border. No pressure was applied. A patch of submucosa was moistened with thrombin and applied to the bowel on the line of the anastomosis had been put about an inch from the line of the anastomosis. *Time of death*—at about 36 hours. At postmortem there was a slight peritonitis present. The graft had stuck on well but there was a leak at the mesenteric border. The submucosal graft was well adherent to the bowel.

Experiment 6. A free omental graft about 3 inches by an inch was dried and a small amount of thrombin solution applied and then it was wrapped around the bowel on the site of the anastomosis—no pressure being applied. *Time of death*—at about 24 hours. Some of the graft had not adhered. No definite leakage could be found.

Group B

Experiment 7. A graft of peritoneum plus muscle about three-quarters of an inch wide and an inch and a half long was swabbed with 3 or 4 drops of thrombin solution on its peritoneal side which was then applied to the line of anastomosis which had been swabbed with plasma. The graft was pressed into position by two clamps for 5 minutes. *Time of death*—this was pressed into position by two clamps for 5 minutes. The animal was frisky and well on the sixth day when it was killed. *Postmortem report*—a wound abscess was present, but there was no peritonitis and the graft had stuck on well and surrounding small bowel had also adhered to one side of the graft.

Experiment 8. A strip of peritoneum half an inch wide and 3 inches long which had a hole in the middle of it (made on taking it from the abdominal wall) was applied to the bowel on which plasma had been swabbed after having been moistened with 3 or 4 drops of thrombin solution. It was held in position with two clamps and on removing the clamps after 5 minutes the graft had stuck on well to the flattened bowel. *Time of death*—about 72 hours. *Postmortem report*—there was a general peritonitis present. The graft had still stuck firmly in position and could not be pulled off but through the hole in the center of the graft feces had contaminated the peritoneal cavity.

Experiment 9. A strip of peritoneum half an inch wide and 3 inches long was moistened with thrombin and held over the suture line with a pressure clamp for 5 minutes. *Time of death*—48 hours. *Postmortem report*—a very extensive hemorrhage into the peritoneal cavity but with no soiling or peritonitis, and the graft was still firmly in position with no leakage apparent.

Experiment 10. A three-quarter inch by 1 inch strip of anterior peritoneum was wrapped around the bowel two and a half times after having been moistened with plasma, and the bowel having been swabbed with plasma, it was clamped on for 5 minutes with a pressure clamp, and then thrombin solution was swabbed on it stuck on well. Then thrombin and plasma was put over the some of the greater omentum and graft and on the graft. The omentum was wrapped loosely round the anastomosis area. *Time of death*—dog was very well and frisky and was killed on the sixth day. *Postmortem report*—no

peritonitis was present and the omentum was wrapped irremovably around the grafted bowel and the graft was also firmly fixed in position.

The possible human applications of these findings on dogs and the human bowel are that with the usual methods of anastomosis as used in either gastroenterostomy operations on the esophagus, gastrorectomy closure of the duodenal stump and small or large bowel anastomoses, the suture line can be very rapidly reinforced by a strip of anterior peritoneum sufficient to go round the bowel and with a little to spare and about three-quarters to an inch in width. This would be moistened with a few drops of a solution of 5000 units of thrombin in 5 cubic centimeters of saline and applied to the suture line which has been swabbed with pooled human plasma, most conveniently obtained from a blood bank. Both these solutions keep a long while in the refrigerator and indefinitely in the desiccated form. This procedure could be done whether or not there is peritoneum on the suture line. Pressure would then be applied for 5 minutes by medium of some such type of clamp as used by the author (Fig. 8) and then the intestines would be carefully returned to the abdominal cavity if handled roughly in its early stages, the graft may be rubbed off before becoming firm. As a further precaution and where anatomically possible omentum could be moistened with thrombin and applied to graft and bowel which has been painted with plasma. This will then adhere and form artificial adhesions as was shown in experiments 10 and 2. Thus a rapid and easy means of omental reinforcement of suture lines is available. Further for some time it has been the practice of the author before suturing to moisten with thrombin solution one side of intestines being anastomosed and the other side with plasma solution. Thus the normal sealing and repair of bowel are speeded up during the few important hours when the bowel is quiescent following laparotomy.

SUMMARY AND CONCLUSIONS

The theoretical basis of a quick, easy method of increasing the safety and scope of a gastrointestinal tract anastomosis is described. Experimental results in dogs and application in a human being are brought forward in support of this method.

UTILIZATION OF HENLE'S LIGAMENT ILIOPUBIC TRACT APONEUROSIS TRANSVERSUS ABDOMINIS AND COOPER'S LIGAMENT IN INGUINAL HERNIORRHAPHY

A Report of 162 Consecutive Cases

JOHN H. CLARK, M.D. Major M.C., AUS., Vernal Utah, and EDWARD L. HASHIMOTO M.D. Salt Lake City Utah

IN November of 1943 because of the urgent need for replacements in the Army it was decided to induct those men who previously had been deferred because of inguinal hernias. The Station Hospital, Fort Douglas, Utah was called upon to rehabilitate many of these men as it is adjacent to a reception center and it seemed advisable to keep them near home until they could undertake basic training.

To plan an operative technique that would make recurrence under the strain of training and combat less likely we decided to review available hospital operative records on recurrent hernias to determine the point at which they had broken through the abdominal wall. It was found that 75 per cent had occurred as direct hernias superior to the pubic tubercle, and posterior to the external abdominal inguinal ring (Fig. 3). The remainder had occurred as indirect hernias probably from incomplete obliteration of the sac.

Many of the standard methods of repair of inguinal hernias have employed the principle of suturing the conjoint tendon to the inguinal ligament to reinforce the posterior wall of the inguinal canal. Surprisingly little attention has been paid to the utilization of other tough tissues that exist in this area, namely the strengthening fibers in the transversalis fascia.

McVay and Anson have recently called attention to the anatomy of the inguinal region and have reanalyzed the structures in that area. They have found considerable variation between their careful dissections and the descriptions ordinarily occurring in standard textbooks, particularly with reference to the transversalis fascia and the conjoint tendon.

TRANSVERSALIS FASCIA

Most texts inadequately describe the transversalis fascia as a structure lining the inner sur-

face of the abdominal musculature (Fig. 3). In our dissections of the inguinal area we found that the transversalis fascia consists of three prominent fibrous structures with intervening connective tissue. These three fibrous reinforcements of the transversalis fascia are the iliopubic tract, Henle's ligament, and the aponeurosis of the transversus abdominis. For a more detailed description of the anatomy the work of McVay and Anson should be consulted.

Iliopubic tract. The transversalis fascia is directly continued into the thigh as a part of the femoral sheath. When this fascia is dissected from the inguinal ligament, care being taken not to open the fascia, there is a band of fibers paralleling the inguinal ligament and demarcating the abdominal component of the fascia from that of the thigh. It can be palpated as a tough, fibrous structure posterior to and separate from the inguinal ligament and cannot be seen unless it is separated from that ligament (Fig. 4). The tract is best seen anatomically by severing and retracting the inguinal ligament (Fig. 5). It is of considerable strength, passes inferior to the internal abdominal inguinal ring and may be traced from the iliopectineus (pectus) fascia in the area of the anterior inferior iliac spine to the pubic tubercle (Figs. 2, 3). Medially blending with Henle's ligament, the aponeurosis of the transversus abdominis and other less prominent portions of the transversalis fascia, the fibers of this tract insert into the pubic tubercle and Cooper's ligament (Figs. 5, 6). This band of fibers of the transversalis fascia, the iliopubic tract, has always been present and was easily identified. It is a separate structure from the inguinal ligament.

Henle's ligament. Without entering into any historical controversy concerning Henle's ligament (McVay *et al.*) we found in all of our dissections a definite fibrous structure, which seemed to be derived in part from the lowermost portion of the lateral border of the rectus sheath, and in

From the Department of Anatomy, University of Utah School of Medicine, Salt Lake City and the Station Hospital, Fort Douglas, Utah.

Fig 1

Fig 2

Fig 3

Fig 4

part from the lowermost extent of the aponeurosis of the transversus abdominis (Fig 3). Fanning out inferolaterally it intermingled intimately with the fibers of the iliopubic tract (Fig 5). This is the structure originally described by Henle.

Aponeurosis of the transversus abdominis The lowermost fibers of insertion of the transversus abdominis muscle are aponeurotic and appear as a flat band paralleling the lateral border of the rectus sheath (Figs 3, 5). Superiorly some of the fibers pass anterior to the rectus abdominis muscle and form part of the anterior wall of the rectus sheath while inferiorly some pass down to blend with Henle's ligament. The major portion of these fibers, however insert into the pecten of the pubis (Fig 6).

CONJOINED TENDON

In our experience both in the dissecting room and the operating room wide variations in the

structure and appearance of the conjoined tendon have been noted. The normal anatomy of the conjoined tendon as described in textbooks, was frequently observed although often it was difficult to differentiate the conjoined tendon from the lateral border of the rectus sheath. Classically the conjoined tendon is described as a common tendon of those fibers of the internal oblique and transversus abdominis muscles which form an arch over the spermatic cord (round ligament in the female) and insert into the pubic tubercle and the pecten of the pubis. More careful analysis of our dissections show that this so-called tendon is composed of two sheets of tissue representing those portions of the aponeurosis of insertion of the internal oblique and transversus abdominis muscles lying anterior and in small part lateral to the rectus abdominis muscle insertion. These two aponeuroses are not a fused tendon as usually described but two distinctly separable aponeuroses.

Fig. 5

Fig. 6

Fig. 7

Fig. 8

Some of our past difficulties in explaining the conjoined tendon to ourselves and to the discerning student lay in the fact that the aponeurotic insertion of the internal oblique failed to reach the pubic tubercle or the pecten of the pubis, but inserted into the anterior rectus sheath interdigitating with fibers of its fellow several centimeters above the usual point of insertion. Moreover in some dissections it was found that the aponeurotic insertion of the transversus abdominis was into the lateral wall of the rectus sheath as described by Robins. These abnormal insertions of the internal oblique and transversus abdominis muscles leave a weakened area superior to the pubic tubercle and posterior to the external abdominal inguinal ring (Fig. 3) the site of most recurrent hernias (Babcock, and Robins). The only structure present in many of these dissections reinforcing this area was a weakened transversalis fascia.

COOPER'S LIGAMENT

In addition to the structures described another important ligament exists, which extends from the pubic tubercle along the pecten of the pubis

and continues posteriorly along the iliopectineal line at an angle of approximately 30 degrees to the inguinal ligament (Figs. 1 & 2). It disappears near the iliopectineal eminence by blending with the periosteum of the bone, and is intimately adherent to the bone in its entire extent. Because of its strength and position it would seem only logical that it must have considerable importance. To it are attached from below upward the pectineal fascia, the lacunar ligament, the aponeurotic thickening of the transversus abdominis, Heale's ligament and the remaining less distinct portions of the transversalis fascia (Figs. 5, 6).

Harkins and Swenson have reviewed the literature and pointed out that the suturing of the transversalis fascia and attached structures to Cooper's ligament was not new. Such men as Narath (1898), Lotheisen (1898), Fischer (1919), Groves (1923), Stetten (1923), Andrews (1924), Keynes (1927), Babcock (1927), Dickson (1936), McVay and Anson (1938-42), Gohard (1939), McClure and Fallis (1939), Amendola (1941), Neubof (1942) and Harkins *et al.* (1943) have used this structure, and been satisfied with its importance in the repair of hernias of this region.

THE REPAIR

The technique presented herein has been developed and tested on 162 inguinal hernias of all types. To date there have been no recurrences. At the time this work was started we were not aware of McVay's operation.

Unless contraindicated all of our herniorrhaphies are done under spinal anesthesia. Regardless of the type of hernia to be repaired a skin incision is made as originally described by Bassini clamping the superficial vessels before they are severed. The aponeurosis of the external oblique is cleaned of all fat and areolar tissue by sharp dissection, and a small incision is made in the direction of the fibers of the external oblique, near the upper margin of the wound. The incision is carefully enlarged with scissors until the ilio-inguinal nerve is exposed and dissected free, and the iliohypogastric nerve is identified. (Damage to these nerves may result in an annoying skin anesthesia and a loss of tone of the internal oblique and transversus abdominis muscles favoring a recurrence of the hernia.)

The incision is then extended down through the external ring and with a moist gauze sponge, the aponeurosis is cleaned down to its insertion. The pubic tubercle is clearly identified and all areolar tissue is cleaned from it with a sponge. The sheath of the cremaster muscle is not opened but is detached from the inguinal ligament with a moist sponge. After the cord has been mobilized, it is held with an Allis forcep if small or with a rubber tape if large enough to be constricted by an Allis.

The indirect sac is identified and picked up at the anteromedial surface of the cord. It is incised and freed from the surrounding structures by sharp and blunt dissection. Exploration is carried out through the incision in the indirect sac for a direct sac, and if one is found it is transposed lateral to the epigastric vessels, converting both sacs into one (Hoguet). It is necessary to identify the inferior epigastric vessels and to separate some preperitoneal fat from the indirect sac and to visualize and dissect the bladder away from a large direct sac before dissection of the sac is complete. Failure to do so may result in a recurrence of the hernia. The sac is closed with a pursestring suture and usually transfixed under the transversalis fascia and internal oblique muscle although this step may not be necessary if the sac dissection is complete.

In order to avoid subsequent confusion in the identification of the structures used in the repair the internal abdominal oblique muscle is identified and held with an Allis forcep. This step

avoids later inadvertent suture of the muscle and its aponeurosis to the deeper structures.

Next Cooper's ligament is palpated as a tough, ridge-like band extending from the pubic tubercle along the iliopectineal line (Figs. 1, 2). The transversalis fascia is then separated from the inguinal ligament and the underlying lacunar ligament in the area adjacent to the pubic tubercle by means of a small straight forceps (Fig. 3) and the anterior 2 centimeters of Cooper's ligament exposed (Fig. 4). Unless this separation is carried out close to the pubic tubercle the transversalis fascia will be entered and preperitoneal fat encountered, so as to interfere with subsequent suture (Trowbridge).

Further digital separation of the transversalis fascia from the inguinal ligament exposes a tough fibrous structure the iliopectineal tract and the underlying femoral sheath (Figs. 4, 5, 6). By clearly exposing the iliopectineal tract and mobilizing the femoral sheath a procedure not previously described in the literature, we avoid accidental injury to the femoral vein or artery (Figs. 2, 5).

Galile transplants of fascia lata, obtained with a Mason fascia stripper are preferred to any other suture material for recurrent direct and scrotal indirect hernias. When fascia lata is used the first strip (1 centimeter wide and 15 to 20 centimeters long) is anchored into the peritoneum and tough structures overlying the pubic tubercle (Fig. 7). From this point a continuous running fascial suture is used. Henle's ligament is then brought down to Cooper's ligament. Next the Galile needle is passed successively through Henle's ligament, Cooper's ligament and the medial portion of the iliopectineal tract closing the weakened area in the transversalis fascia, the site of most recurrent hernias. At the same time, the iliopectineal tract is displaced, shortened and drawn diagonally across the area occupied by the femoral canal, to close the canal (Figs. 1, 2, 3, 7). This procedure is technically less difficult than suturing the aponeurosis of the transversus abdominis in Cooper's ligament in the relatively inaccessible region of the femoral vein (McVay 1942) and permits clear visualization of all structures used in the repair. The suture is continued (Fig. 7) attaching the lowermost margin of the aponeurosis of the transversus abdominis to the iliopectineal tract, folding under and obliterating the relatively weaker areas of the transversalis fascia. When the internal abdominal inguinal ring is reached it may be closed tightly without encircling the dangerous circulation of the cord. The end of the fascial strip is then anchored with interrupted No. 40 cotton sutures.

The same technique is employed in less difficult repairs with interrupted No. 30 cotton sutures.

This repair of the transversalis fascia and its reinforcing structures produces a strong barrier to recurrence of hernias. While there may be no necessity for further repair of overlying structures (McVay *et al.*) on the other hand, in most cases it is a very simple procedure to suture the lowermost margin of the internal abdominal oblique muscle and its aponeurosis to the inguinal ligament, by means of a fascial strip or interrupted No. 30 cotton sutures, after the method of Bassini (Fig. 8). We do not hesitate to use muscle for this second layer when the aponeurosis is deficient. Dissections of recurrent hernias have convinced us that the epimysium of the muscle will become firmly adherent to the inguinal ligament. Occasionally it is found that the anomalous aponeurotic insertion of the internal abdominal oblique muscle cannot be easily approximated to the inguinal ligament. In that event a relaxing incision in the rectus sheath is made (Rienhoff) and the fascia overlying the pyramidalis muscle, the lateral border of the rectus sheath and available fibers of the internal abdominal oblique and its aponeurosis are then sutured to the shelving margin of the inguinal ligament. Either method of suture produces an additional strong barrier and although we feel that the second layer is the least important of the two nevertheless, the Bassini operation has cured many thousands of cases. Therefore, we have used this additional precaution.

The aponeurosis of the external oblique is repaired loosely over the spermatic cord, and the external inguinal ring is not made unduly small. We do not believe that the aponeurosis of the external oblique can be of much significance as a barrier to recurrent hernias, once the posterior wall of the inguinal canal has broken down.

SUMMARY

With certain anatomical facts as a basis for a rational reconstruction of an inguinal hernia, the described operation was devised. It completely closes the weak area superior to the pubic tubercle and posterior to the external abdominal inguinal ring. The salient features are

1. By separating the loosely attached transversalis fascia from the inguinal and lacunar ligaments at their most inferior portion (close to the pubic tubercle) and stripping the fascia from the ligaments, a strong band of fibers is exposed the iliopectic tract (Figs. 3, 4, 6)

2. As an initial step Henle's Ligament and adjacent portions of the aponeurosis of the transversus abdominis are sutured to Cooper's Ligament along its anterior one-third, an available surface of approximately 2 centimeters. This results in no undue tension, whereas, suturing these structures to the entire length of the ligament, namely back to the area of the femoral vein, does result in a definite tension and requires a relaxing incision in the rectus sheath.

3. The weak area of the transversalis fascia is further strengthened by attaching the transversus abdominis aponeurosis to the iliopectic tract as far as the internal abdominal inguinal ring (Fig. 7). This produces a strong pleat of transversalis fascia and raises and displaces the iliopectic tract closing the former defect (Fig. 7). At the same time this step produces a tight internal abdominal ring and closes the femoral canal.

4. A second barrier may be constructed by suturing the aponeurotic lower fibers of the internal oblique muscle to the inguinal ligament after the method of Bassini. If this aponeurosis should be deficient, a suture in the rectus sheath or in the aponeurosis of the transversus abdominis is taken, medial to that described in paragraph 3, and this layer sutured to the inguinal ligament. Rarely a relaxing incision in the rectus sheath required.

5. The aponeurosis of the external oblique is repaired loosely over the spermatic cord, and the external abdominal inguinal ring is not made unduly small.

6. Strips of fascia lata have been found to be the most suitable suture material for the repair of recurrent, direct, and large scrotal indirect hernias.

EARLY POSTOPERATIVE RISING

A Statistical Study of Hospital Complications

JAMES B BLODGETT M D and EDWARD J BEATTIE, M D Boston Massachusetts

THERE has recently been a revival of interest in early postoperative rising and walking. In June 1942 a critical study of early postoperative ambulation was undertaken at the Peter Bent Brigham Hospital. The preliminary results of these studies are the basis for this communication.

Ries in 1899 was the first to report on the subject of early postoperative rising. He had noted that his gynecological patients who rose from bed shortly after operation were considerably stronger than as a group they had a low incidence of post operative complications and that there were no demonstrable ill effects of early rising. The early rising technique was not then widely accepted in this country but in continental Europe it has been extensively used from 1909 until the present time. The recent revival of American interest in this subject began in 1941 when Leithauer (4) reported a series of 436 cases. Newburger (5) has published an excellent review of the American and foreign literature on the subject and also experimental data of his own (6) from rats. Newburger's experiments showed increased strength in wounds of animals in the early postoperative period if they had been given postoperative exercise. Clinical papers have been published by Leithauer (3) Nelson Nixon Powers, D'Ingianni, and Schafer and Dragstedt. All these authors are impressed by the rapid return to full strength of their early rising postoperative patients and by the apparent early reduction of wound discomfort. Almost all of them note a low incidence of pulmonary complications and of deep phlebitis of the legs. The latter three reports are the only ones in which any comparisons are drawn between a series of early rising patients and a control series. The definition of what constitutes early rising has not been very strict as some authors include in this group patients who have risen as late as the 4th or 5th day after operation.

In order to arrive at an accurate appraisal of the results of early rising cases must be compared under as similar circumstances as possible. Since the incidence of pulmonary and vascular complications appears to vary in different parts of the

country the results of an early rising series in one region cannot properly be compared with those of a control series from a different region. The two series are most accurately comparable if they are observed in the same clinic.

METHOD

In order to emphasize any apparent changes in postoperative complications this study is limited to the type of operative case in which the complications most commonly occur that is, patients having major abdominal surgery. Only patients who rose from bed either on the first or second postoperative day are considered in the group of early risers. These are compared with patients who remained in bed at least 1 week after operation.

This study compares 238 consecutive cases in which early rising was practiced with 443 in which it was not. The factors considered as possibly bearing on the incidence of complications were (1) age, (2) sex (3) type of anesthesia, (4) type of incision (upper vertical lower vertical and McBurney).

The operations performed through upper abdominal incisions were on the biliary tract stomach duodenum and spleen. The operations through lower incisions were on the small and large bowel female internal genitalia, and occasionally the appendix. The procedures through McBurney incisions were all appendicectomies. The suture technique was that of interrupted fine silk to all layers except the peritoneum where continuous chromic catgut was used.

The complications studied were (1) pulmonary (atelectasis, pneumonia) (2) vascular (phlebitis, pulmonary infarct) (3) wound (disruption, infection).

Our technique of getting the patients up from bed is modeled after Leithauer (4). The patient is turned upon the side on which he has his incision. The hips and knees are flexed. Thus the knees and lower legs are brought to the edge of the bed. The patient is then raised sideways to a sitting position on the side of the bed. The advantage of sitting up in this manner is that as the patient assists in raising himself he uses the flank muscles on the side opposite from his wound. As the patient sits on the side of the bed his shoes are

TABLE I—ANALYSIS OF COMPLICATIONS IN EARLY AND NON-EARLY RISING PATIENTS

put on and then he stands up on a foot stool¹ While standing on the foot stool, he is encouraged to breathe deeply and to cough several times after deep inspiration. This procedure is less painful than when the patient coughs in bed and is often effective in raising mucous plugs from the bronchi. He is now encouraged to walk 8 or 10 feet before sitting in a chair. On the first rising the patient remains in the chair about 10 minutes, and then returns to bed in the same manner as he rose. Our patients were gotten up twice each day. Usually by the third or fourth day they needed little or no assistance and could rise at will. All the patients were encouraged to move freely about in bed and to breathe deeply several times each hour.

RESULTS

The most striking effect observed in early rising patients is the rapidity with which they regain their strength. In point of fact, they do not seem to lose strength. They are more active in bed, and their wounds are less disabling. On the fourth postoperative day most of the early rising patients had very little wound discomfort and got up unassisted. At this time they became ambulatory patients and required very little nursing care. As a result of this early strength and freedom from pain, most of the patients requested that they go

home earlier than the non-early rising patients. We did not feel justified in sending our patients home before the seventh to ninth postoperative day because not until then could we consider that the time for appearance of wound infection or disruption had passed. In spite of this, 64 per cent of the early rising patients were discharged before the 13th postoperative day while only 26 per cent of the control group were discharged by this time. At the time of discharge, those of the early rising group were strong and able to do a great deal for themselves in contrast to the group who had remained in bed for 10 to 14 days and were usually discharged 1 or 2 days after getting out of bed.

INCIDENCE OF COMPLICATIONS

Table I lists the overall incidence of complications. The complications in the patients who rose on the second day are separated from those who rose on the first day so that a more accurate picture will be given. As this study was begun, we were concerned lest there be a marked increase in the incidence of wound disruption among the early rising group. It is seen that instead of increased incidence of wound disruption, the early rising group had a slightly lower incidence of wound disruption. Likewise the incidence of pulmonary complications was reduced. The incidence of vascular complications, however, was somewhat increased. None of these increments are, as yet, significantly greater than the standard error of the difference but they point the trend. The trend

¹ We have considered it important to put on the patient's shoes, or slippers with heels, before he leaves the foot stool. Properly laced against deep relaxation of the leg veins. If the patient is one with short leg cords, he might injure his posterior calf muscles by standing, stepping down from the foot stool, or walking, and a pathological sequence could be initiated that might result in deep phlebitis.

TABLE II.—ANALYSIS OF PULMONARY COMPLICATIONS

	First day rising						Non-early rising					
	Number	Pneumonia		Atelectasis		Total	Number	Pneumonia		Atelectasis		Total
		No.	Per cent	No.	Per cent			No.	Per cent	No.	Per cent

Spinal	30					1	0					1
Total	10						4		7			7
Age												
2-30 yrs.	63						3	4	3	7	5.0	6.5
31-60 yrs.	28			3	10.7	6	6.6	3		8	13	18.6
60 yrs. plus	34			2	5.8	3	8.8	3	0	10		8

toward earlier discharge from the hospital is seen in the greater percentage of the test group who were discharged early. This reduction in hospital days required and the fact that the patients who have risen early need less care represents a definite reduction in work for the ward personnel.

Pulmonary complications. The diagnosis of atelectasis was made in our patients on a clinical basis if there was a postoperative rise in temperature associated with rales and elevated respiratory rate in the absence of other demonstrable cause for fever. The diagnosis was also made if there was x ray evidence of atelectasis. The incidence in the first day rising group was 4.3 per cent, 6.3 per cent in the late rising group.

Table II is a comparative chart of the pulmonary complications analyzed for their various etiological factors. The familiar greater incidence of atelectasis in upper abdominal vertical wounds is seen in both groups when the cases are divided with respect to the location of the abdominal wound. It is significant that no case of atelectasis occurred in the cases with low abdominal wounds who rose on the first day.

Analysis for the sex factor shows that although the incidence of atelectasis in men who remained in bed was high it was unusually low in those who rose on the first day after operation. The incidence of atelectasis among the females of the two groups is essentially the same.

The analysis for the type of anesthesia shows no significant variation in the incidence of atelectasis

in either group whether ether or spinal anesthesia was used.

The influence of the age factor repeats the familiar pattern of increasing incidence of atelectasis with advancing age in both groups.

Pneumonia was such an infrequent complication that it does not permit comparative analysis.

Vascular complications. The term phlebitis is used in this discussion to include both silent thrombosis (phlebothrombosis) and deep phlebitis of the legs. The diagnosis of deep leg vein phlebitis was made on the basis of tenderness in the calf muscles, associated usually with one or more other signs i.e. a positive dorsiflexion (Homans') sign, edema of the lower leg, or a rise in pulse rate, temperature, or white count. Also if a patient had pulmonary infarct or embolism in the absence of heart disease, a presumptive diagnosis of phlebitis was made. The overall incidence of deep vein phlebitis among the early rising patients is seen to be greater than among those who did not rise early (3.2 per cent vs. 1.8 per cent). See Table III.

Analysis of the incidence of phlebitis with respect to the placement of wounds shows that there was no phlebitis recorded in any of the McBurney incisions whether they rose early or not. The females had a higher incidence of phlebitis than the males in the first day rising group. The highest incidence of phlebitis in the non rising group was in the patients of 60 years or more, but in the early rising patients, the highest incidence was in the group between 30 and 60 years.

TABLE III.—ANALYSIS OF VASCULAR COMPLICATIONS

	First day rising					Non-early rising				
	Number	Phlebitis		Infarct		Number	Phlebitis		Infarct	
		No.	Per cent	No.	Per cent		No.	Per cent	No.	Per cent
Incisions (abdominal)

Spiral	39		4			19				
Local	28					24				
Age										
1-20 yrs.	63		4		4	195				
21-40 yrs.	23	2	2.7		2	123		4		
41 yrs. plus	34					86	7	3		1

This observed increase in the incidence of post operative deep phlebitis of the legs is not great enough to be of irrefutable statistical significance. But it is significant that our data do not agree with many of the previously published clinical impressions that early rising produces a reduction in the incidence of phlebitis. Early rising is apparently not the answer to the problem of postoperative venous thrombosis.

WOUND COMPLICATIONS

Considerable interest was attached to the possibility of increase in wound disruption which might occur from the increased stress put upon the wound in rising from the bed and walking about. Wound disruption is here defined as any wound in which the fascia is shown to have separated whether or not the peritoneum remained intact. Our data (Table IV) show an actual reduction

TABLE IV.—ANALYSIS OF WOUND COMPLICATIONS

41 yrs. plus	34		9		9	86		3		1

wound disruption in the test group. Among early rising patients there was 1.1 per cent of wound disruption whereas in the non-rising patients, there was 2.8 per cent incidence of wound disruption. The known higher incidence of wound disruption in upper abdominal incisions was demonstrated in both series. The two McBurney incisions that had wound disruption were those in which drains had been used.

The incidence of wound infection among the early rising patients was 2.7 per cent as compared with 5.7 per cent in the patients who rose late. This group includes all types of infection including stitch abscesses.

It is interesting to note that all of the wound infections in both series appeared in patients with potentially contaminated wounds. Of the 5 patients who had infected wounds in the early rising group there were 4 patients who had cholecystectomies and 1 patient who had an appendectomy for acute appendicitis. Of the 25 patients who had infected wounds in the non-early rising group 11 had appendectomies, 10 cholecystectomies, 1 a perforated ulcer and 3 a resection of the large bowel.

EVALUATION

We have now observed the technique of early postoperative rising for 3 years. Data on a control series of intra-abdominal operations are presented herewith. The most remarkable observation is that postoperative activity tends to maintain the patient's strength and endurance whereas prolonged rest leads to increasing weakness and muscle atrophy. It also appears that muscle activity in the region of the wound has the tendency to reduce the period of wound tenderness but it does not increase the incidence of wound disruption.

Early rising appears to reduce the incidence of postoperative atelectasis. This may be due to increased respiration and more effective coughing, especially when the patient is standing when his diaphragm can descend to lower levels (3). Since atelectasis most frequently appears during the first 48 hours after operation, the patient should be gotten up as soon as possible within that period if rising is to have a significant effect on preventing atelectasis.

In our experience¹ the incidence of phlebitis or phlebotrombosis of the deep veins in the legs is not reduced by early postoperative walking. Our data agree with the published impression of D'Inganni who observed early rising patients in New Orleans. There may be certain precautions which can be observed to minimize calf muscle trauma when patients rise from bed. These are however equally important at any time in the postoperative period.

There was no greater incidence of wound disruption and infection in our patients who rose early.

SUMMARY

A controlled, preliminary study of early postoperative rising and walking is made on patients having major intra abdominal surgery. A total of 681 cases were analyzed for postoperative complications and their causative factors. Early rising is defined as rising and walking on the first or second postoperative day.

The patients who rose early were considerably stronger and had less pain in their wounds. They were able to care for themselves on about the fourth postoperative day and were ready for discharge considerably earlier than the control group.

The incidence of wound disruption and wound infection was reduced in the early rising group.

The incidence of pulmonary complications was somewhat lower in the early rising group.

The incidence of deep leg vein thrombophlebitis was observed to be somewhat greater in the early rising group.

It might be postulated that some of the late rising group developed signs of phlebitis of the leg veins at home several days after discharge. If so, it has not been apparent in the follow-up visits which are made days to weeks after discharge.

RESTORATION OF CONTINUITY VERSUS CURE IN CARCINOMA OF THE RECTUM

THERE is a widespread revival of operations designed to preserve the rectal sphincter in patients with carcinoma of the rectum and rectosigmoid. This aim to preserve the sphincter is a natural outcome of advanced surgical skill and technique on the one hand, and on the other of evidence that primary spread of disease from this region is cephalward. At this time we must carefully weigh the evidence of experience and adopt a rational attitude regarding the problem.

Given a patient with carcinoma of the rectum we must take into consideration the single fact that cure if possible is our obligation. Unfortunately many of these victims arrive in an incurable condition—a fact due mainly to our inadequate educational methods, although at the moment there seems

to be no effective manner in which all cases can be diagnosed in an early state.

In a recent series of 100 consecutive patients with carcinoma of the rectum the average duration of disease before entry into the Massachusetts General Hospital was 18 months. Twenty-eight had such extensive disease that a resection was impossible. Seventy-two had an abdominoperineal resection in one or two stages. There were two deaths in this group—a postoperative mortality of 2.8 per cent. One patient died from hypertensive heart disease, and the other of a pulmonary infarct. About 10 per cent of the resections were done in the presence of hepatic metastases. Including the operative deaths, approximately 45 per cent of the operable cases or 30 per cent of the entire group will live 5 or more years. It appears at this time that only earlier diagnosis will materially improve these results.

The best safest, and most adaptable operation so far devised is the combined abdominoperineal resection of Miles. The Miles technique may be varied in many ways and the operation may be done in one or two stages. This method allows the surgeon to remove the local spread of the disease including the regional lymph nodes and extension to neighboring viscera as well as to perineal muscles. In skilled hands, the mortality rate is low and the morbidity is growing less with better preparation and after-care. This procedure however does leave the patient with a permanent colostomy.

Colostomy is not burdensome to thousands of grateful individuals who have been cured of cancer. With reasonable care they are free to carry on their business, athletic and

EDITORIALS

social functions without offense or inconvenience. Sentimental abhorrence of the colostomy by patient and physician has wasted many useful lives. Although none looks forward to a colostomy life with avid joy few will refuse it if the entire situation is explained to them. Taught the simple principles concerning care of the colostomy nearly all of these patients are comfortable and happy.

In performing resections with low anastomosis, one must consider the following rules governing a proper operation for malignant disease. First, have we given the individual patient his greatest chance for cure? Second have we increased his immediate hazard? Third will the morbidity from poor sphincter control or fistula formation justify the procedure? The second and third of these have

been pretty adequately answered in a satisfactory manner. The first concept is not yet determined and it will take considerable time to do so. In reporting results on these procedures surgeons must make it clear that local recurrences have not taken place in those patients whom they would have expected to cure by performing a complete extirpation of the rectum and the muscles of the perineal floor.

The issue is confused by the fact that all of us agree that restoration of continuity is justifiable if the patient has metastatic disease in the liver at the time of operation. These cases should not be considered in the same light as those whose spread of disease was limited to the resectable area at the time surgery was undertaken.

ARTHUR W. ALLEN

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE book entitled *Penicillin in the Treatment of Infections*¹ by Keefer and Anderson presents in its 48 pages a clear summary of what is known of penicillin and its effect, but it does not disclose any new facts about its action or administration.

Penicillin seems to act like the sulfonamides by interfering with some metabolic processes of susceptible bacteria and therefore is active only when the bacteria are in a phase of growth and multiplication. In the concentrations that are achieved in living beings its effect is chiefly bacteriostatic and not bacteriocidal. Thus it does not actually eliminate the infecting organisms but inhibits their growth and multiplication. But unlike the sulfonamides, penicillin is not inhibited by pus, peptones, or the breakdown products of tissue autolysis. The sensitivity to penicillin varies with the various species of organisms. It is not understood yet why gram negative bacilli and virus infections are not susceptible to the action of the drug nor why susceptible bacteria may become resistant when exposed to the drug for longer periods. However it has been shown that certain bacteria of the coli group produce a substance penicillinase, which inactivates penicillin. The sensitivity of any bacterial strain to penicillin can be determined and may be very useful in the treatments of certain infections. Of considerable importance is the fact that there is no correlation between resistance to penicillin and resistance to the sulfonamides.

Several biological assay methods for determining the concentration of penicillin in the blood and the body fluids are available. It has been found that 60 per cent of the amount of penicillin injected in the blood stream or the muscles were excreted in the urine within 1 hour and that little or no drug remained in the blood after 3 hours. For this reason, it became evident that the use of large doses of the drug was wasteful since a better bacteriostatic level could be maintained in the blood by the administration of small doses given every 2 to 3 hours. It has also been shown that when mixtures of penicillin in beeswax and peanut oil were injected intramuscularly, the drug was absorbed slowly and the therapeutic effect could thus be prolonged to 6 or 7 hours. The authors recommend for the treatment of systemic infections the intermittent intramuscular administration of penicillin. Intermittent intravenous

infections or continuous intravenous or intracerebral infusions offer no advantages and are considerably less convenient.

The passage of penicillin from the blood into the cerebrospinal fluid or the various parts of the eye is minimal and noneffective. Its passage into the pleural, abdominal and synovial cavities is somewhat more satisfactory. It is therefore recommended to inject penicillin directly into the subarachnoid space, the cerebral ventricles, the articulations, the pleural cavity, the cranial sinuses, the chambers of the eye, etc. Topical application of penicillin to superficial burns skin infections, and infected wounds by means of wet dressings or rubber catheter has given excellent results. The dosage and the most adequate way of administration are discussed for the various methods of administration of penicillin, and the clinical aspect of penicillin therapy is presented with more details in cases of staphylococcal bacteremia of the face, acute hematogenous osteomyelitis, chronic osteomyelitis, staphylococcal pneumonia, multiple subcutaneous abscesses, hemolytic streptococcal pneumonia and empyema, gonorrhea, meningococemia, pneumococcal pneumonia, pneumococcal meningitis, subacute bacterial endocarditis, gas gangrene and syphilis. The toxic reactions are rare, the more common being urticaria and fever.

Penicillin is without doubt the most effective agent for the treatment of infectious diseases. However it should not replace or diminish strict surgical asepsis, the early surgical treatment of wounds, and general medical prophylaxis against infectious diseases.

GEORGE PRINCE

AMONG the noteworthy publications of the Medical Department of the United States Army *Pathology of Tropical Diseases*² by Ash and Spitz will find a place in the first rank. It fills a need met by textbooks on tropical medicine, which rightfully place emphasis on etiology, clinical features, epidemiology, diagnosis, and treatment. This atlas, which is a collection of 641 photographs, photomicrographs, roentgenograms, and drawings, offers visual material in highly acceptable form. It is obvious that the authors had a wealth of material at hand, because nearly every illustration is one of the best possible. The technical quality of the reproductions is uniformly good. There is no doubt but that the publisher took the greatest pains to make this book as nearly perfect as he could.

¹ *PENICILLIN IN THE TREATMENT OF INFECTIONS*. By Chester S. Keefer, B.S., M.S., M.D., Sc.D. (Bos.), and Donald G. Anderson, A.B., M.D. New York, London, Toronto. Edited by Henry A. Charles, A.M., M.D., LL.D., Sc.D. (Hon.). P.A.C.F. Hon. F.R.C.P. (Can.) Oxford University Press, 1943.

² *PATHOLOGY OF TROPICAL DISEASES: A TLAS*. By J. E. Ash, Colonel, M.C. U.S.A., and Stephen Spitz, M.D. C.S. A.U. Philadelphia and London: W. B. Saunders Co. 1943.

REVIEWS OF NEW BOOKS

Nearly every disease to be found in the tropics, from alinlum to yellow fever is dealt with. Brief explanatory notes which include enough information to orient the reader and sketches of the epidemiological facts are provided. The salient features of each disease are presented in excellent photographs or x-ray pictures.

This is an authoritative book. Although atlases are often thought of as supplementary works this particular one is outstanding because it is a highly intelligent contribution designed specifically to illuminate where illumination is most needed. It is recommended to students of tropical medicine and to pathologists who will be confronted with the sequelae of tropical diseases.

HENRY R. JACOBS

A LONG standing gap has been filled by Thomas and Hadden's *Amputation Prostheses* by bringing together two authorities who have combined their knowledge to present a practical guide for surgeons and practitioners on the proper use of prosthetic appliances. This dual authorship—a surgeon and a manufacturer of artificial limbs—provides a common ground for discussion of the problems of the amputee.

The mutilating injuries of war have awakened an increased interest in amputations surgical technique and prosthetic appliances. It has been estimated that the number of amputations resulting from the First World War totaled 500,000 for all nations engaged. Amputations among the armed forces of the United States were relatively small, however numbering only about 4,000. During the Civil War there were well in excess of 30,000 amputations in the Union Army alone. Figures for the Second World War released as of July 1, 1945 reveal that over 15,000 amputation cases have been treated in the various amputation centers established by the Army and Navy of the United States and no doubt there will be many more before the toll of the war is ended. The total number of amputations resulting from World War II will probably exceed a million.

The number of amputations performed each year among the civilian population of this country far exceeds amputations performed in the armed forces even in wartime. The American Federation of the Physically Handicapped has estimated that there are approximately 75,000 new amputation cases in this country every year and that of this number 40,000 are major amputations requiring prostheses. The National Safety Council has reported that, prior to World War II 32,500 amputations resulted annually from accidental causes alone. Reliable estimates reveal that there are now approximately 925,000 amputees living in the United States. The artificial limb manufacturers of this country report that prior to the present war they were supplying prostheses to more than 70,000 persons annually.

In the past, too little attention has been paid by surgeons to the problem of the artificial limb which the amputee must wear throughout life. As a result, amputations rarely have been considered from the prosthetic point of view.

There is a great need for closer co-operation between the surgeon and the limbmaker. Occasionally and unfortunately surgeons, through lack of information fail in advising the patient as to his permanent prosthesis or in supervising its fitting. Few surgeons are familiar enough with prosthetic appliances or limb fitting to give such advice.

There is a definite need for a practical text devoted to the amputation prosthesis. Such a text to be of value, should be concerned primarily with principles of fitting and aligning the prosthesis and with instructions as to its use. In this book, the surgeon and limbmaker have collaborated combining the scientific knowledge and training of the surgeon with the mechanical skill and practical experience of the limbmaker in order to give to the physician and the limbmaker alike a practical manual on the selection fitting, and use of artificial limbs.

In the construction of the amputation prosthesis, emphasis is placed on simplicity of design and lightness of weight with durability. Materials used are important only insofar as they are light and durable and lend themselves readily to the necessary adjustment of alignment and fitting. The choice of materials often will vary according to the individual needs of the amputee depending upon such factors as the site of amputation and the age, sex, occupation, and physical condition of the amputee.

Elaborate and complex joint mechanisms and control, despite extravagant claims of manufacturers and salesmen, are not essential in the average prosthesis. They add considerably to the original cost, are more difficult to adjust and repair and offer few, if any advantages over the more simple standard types. The ordinary amputation prosthesis is really a very simple apparatus mechanically, and if it is properly aligned and fitted it fulfills its functions most satisfactorily without complicated mechanisms.

Of far greater importance than materials and types of joint mechanisms in the successful use of the prosthesis are the proper alignment and fitting of the limb. This requires considerable skill based on experience and judgment, and a thorough understanding of certain fundamental anatomic and physiologic principles. Surgeons and limbmakers alike have been too prone to place undue emphasis on the importance of materials and complex mechanical devices, neglecting the all important principles of alignment and fitting. In this text considerable attention is given to these fundamental principles.

Both the surgeon and limbmaker should guard against unwarranted claims and against encouraging ill founded hopes on the part of the amputee.

One chapter of the text pertains to prostheses for children—a subject which presents certain special problems and which heretofore has been given little or no attention in surgical texts.

A chapter is also devoted to the subject of the rehabilitation of the amputee. Particular emphasis is placed on the importance of the emotional readjustment of the amputee to his handicap. Attention is directed also to the necessity for instruction and training in the proper use of the prosthesis. Vocational guidance and selective placement in employment are also emphasized. Consideration of these problems, so often neglected, are of the greatest importance in the successful rehabilitation of a person handicapped by the loss of an extremity.

Special acknowledgment is given to Captain Henry Kewler MC USNR, for use of photographs and diagrams demonstrating his cineplastic amputations and illustrating postoperative care of the stump preparatory to fitting the prosthesis, as well as for his valuable contribution on the subject of rehabilitation of the amputee.

The text covers the following subjects: development of modern amputation prostheses; the amputation stump; prostheses for amputations of lower extremity; alignment and fitting of lower extremity prostheses; upper extremity prostheses; prostheses for children; and rehabilitation of the amputee.

In comparison with some widely publicized contributions on the same subject, the reader will find the present volume a pleasant relief. The book is remarkably practical throughout. The illustrations are unusually instructive.

PHILIP LUTWY

Movements of the Stomach and Duodenal Bulb indicates that the human stomach consists of four parts. Each part is homologous with each of the four stomachs of ruminants. He suggests that the fourth of the human stomach is homologous with the rumen and the corpus with the reticulum (second stomach). These constitute the longitudinal stomach. The transverse stomach which is usually referred to as the pars pylori, beginning at the incisura, he divides into three parts. The "sinus" fans out downward from the incisura forming the "knee" or "elbow" at the greater curvature. The "membrana angularis" fans out upward from the junction of the sinus with the pyloric canal, to form a bulge on the lesser curvature between the incisura and the pyloric canal. Thus, the sinus and membrana angularis form what is frequently referred to as the pyloric vestibule and the pyloric canal, called the pyloric antrum or "prepyloric region." The duodenal bulb appears to be correlated with the pyloric sphincter, which structure contains a duodenal as well as a gastric component.

His anatomical description of the arrangement of the muscular fibers in the stomach in relation to the pyloric portion of the stomach and sphincter is enlightening.

The book is recommended to all students of the anatomy and physiology of the stomach.

ARTHUR J. ARTHUR

THE MUSCULAR BUILD AND MOVEMENTS OF THE STOMACH AND DUODENAL BULB, ESPECIALLY ITS RELATION TO THE FUNCTION OF THE SEVERAL DIVISIONS OF THE STOMACH IN THE LIGHT OF COMPARISON A STUDY IN ENATOMY. By John Thompson, ChM, FRCGS, F.R.C.S. (Edinburgh) and Frederick Baskerville, 1942.

AS a result of his deductions from a study of the embryology and comparative anatomy of the stomach the author of *The Muscular Build and*

INTERNATIONAL ABSTRACT OF SURGERY

VOLUME 82

APRIL, 1946

NUMBER 4

ABSTRACTS OF CURRENT LITERATURE SURGERY OF THE HEAD AND NECK

EYE

Ridley H.: Ocular Manifestations of Malnutrition in Released Prisoners of War from Thailand. *Brit. J. Ophth.*, 1945 29 613.

The author reports on the unique opportunity offered by the examination of 500 released allied prisoners of war and internees from Thailand who believed that their vision had deteriorated during their captivity. Food had been deficient in quantity and especially lacking in proteins, fats, and vitamins. Meals had consisted mostly of polished rice vegetable stew, a small quantity of meat and tea. For a period of 6 months the food had been reduced nearly to the starvation level, with only rice and salt for one period, and it was during this time that most of the visual symptoms occurred. Ninety of 100 patients were amblyopic.

In many cases the amblyopia had occurred during a single day; in others the onset was more gradual. Night blindness was uncommon. Campimetry revealed in 90 cases a small central scotoma not usually extending over 3 degrees from the fixation point, although in the severe cases it was much larger. Many patients showed normal fundi, but in others a temporal pallor of the disc was noted. Altogether there were 48 definite and 50 doubtful cases of optic atrophy.

Practically all of the released prisoners showed some degree of keratoconjunctival abnormality usually an increased vascularity at the limbus with the formation of aneurysms, and vessels and opacity extending into the cornea for about 2 mm. There were 3 cases of interstitial keratitis with negative Kahn tests.

While there seems no doubt of the relationship of the visual disorders described to the nutritional deficiency the author is inclined not to place the entire blame on a single vitamin deficiency but rather on the general malnutrition of the prisoners. However some of the changes described might well be secondary to deficiency in vitamins of the B group. There was noted a high incidence of arcus senilis in this relatively young age group and this also suggests a derangement in fat metabolism.

Treatment in these cases included a full diet and supplemental vitamin therapy. The author plans to offer a later report showing the results which have been achieved. In the severe cases with marked optic atrophy too much improvement is not to be expected. Visual acuity at the time of the original examination varied from 1/60 to a partial 6/6.

WILLIAM A. MANN M.D.

Sen K., and Ghose, N.: Ocular Gnathostomiasis. *Brit. J. Ophth.*, 1945 29 618.

Few cases of parasites recovered from the eye have been reported. The author reports the first case of gnathostomiasis in the human eye. In fact, this infection is quite rare in the human being and up to 1937 only 24 definite and 60 clinical cases had been reported and these involved the stomach, lungs, kidneys, mastoid and subcutaneous tissues.

The present instance occurred in a 26 year old Hindu who was admitted to the hospital for investigation of an orbital cellulitis with hemorrhages in the retina and vitreous of the left eye. He developed an iritis and after a considerable period of treatment a moving pigmented nodule was noted in the anterior chamber imbedded in the iris. Slit lamp examination revealed it to be a worm.

The parasite was removed after a retrolbulbar injection to reduce the intraocular tension (which had been elevated). After a suitable incision with a thin Grace knife the worm was removed *in toto* with a curette. Recovery was uneventful. Later examination showed the disc to be atrophic and the arteries thin and sheathed, and there was a pigmented scar below the macula. As this was not present on the first examination it was believed to be the point of entrance for the parasite. WILLIAM A. MANN M.D.

Rosen E.: Diabetic Needles. *Brit. J. Ophth.* 1945 29 645.

The author points out that in diabetes characteristic changes can be found in the lens in addition to the accepted ocular signs of diabetes such as rubeosis iridis, small globular hemorrhages at the macula, retinitis proliferans, retinitis circinata, and den onset of hyperopia, and lipemia retinalis.

Fig. 1. In this case the patient had no knowledge of having diabetes. The vision was 20/200 in each eye, and was correctible to 20/30 in each eye. Examination of the lens revealed the presence of diabetic needles. The fundus showed no evidence of diabetes. Urine examination disclosed the presence of sugar.

Fig. 2. In this case the patient was 60 years of age. She had had diabetes for 5 years. Diabetic retinitis was present especially at the macula. In the periphery of each lens there were several diabetic needles superimposed upon the incident cortical opacities.

He describes a lenticular sign in diabetics which when present is considered specific for diabetes. It is known as the diabetic needle or "roman numeral" sign—a linear black spoke in the periphery of the lens which is no thicker centrally than it is peripherally. In all cases the spokes were never thicker at the periphery of the lens than at its center and they were seen best with the indirect ophthalmoscope or the retinoscope.

A series of 10 cases which presented these so-called "diabetic needles" is reported. Many of the cases also presented nuclear and cortical lenticular opacities.

JOSUUA ZUCKERMAN, M.D.

Smelser, G. K., and Ozanian, V.: The Effect of Local Anesthetics on Cell Division and Migration following Thermal Burns of the Cornea. *Arch. Ophthalmol.*, Chic., 1945 34: 271.

Smelser and Ozanian discuss the effect of local anesthetics on cell division and migration following thermal burns of the cornea.

They conclude

1. Topical application of most anesthetics inhibits mitosis in the intact corneal epithelium if they are of a sufficient concentration to produce anesthesia.

2. The inhibition of cell division varies with the drug, the method of administration and the frequency of application.

3. If anesthetics are applied locally to closed burns the migration of epithelial cells over the injured area is markedly inhibited.

4. Most anesthetics also inhibit cell division in the regenerating epithelium.

5. Some drugs inhibit mitosis but do not retard cell migration.

6. Nupercaine and phenacaine ointments produce prolonged surface anesthesia, but do not impair mitosis in normal epithelium nor retard cell division or migration in regenerating epithelium.

7. Unbuffered aqueous solutions inhibit healing more than ointments of the same or of greater strength.

JOSUUA ZUCKERMAN, M.D.

Roper, K. L.: Senile Hyaline Scleral Plaques. *Arch. Ophthalmol.*, Chic., 1945, 34: 253.

The author reviews the literature on a dual asymptomatic entity he calls "senile hyaline scleral plaques" and reports 5 cases of his own. These plaques, which are rectangular, round, or oval and of a slate gray color, are symmetrically situated about 3 mm. from the limbus and about 5 mm. anterior to the insertions of the lateral or more frequently of the medial rectus muscles. The plaques are slightly depressed and translucent. Clearly. Patients are generally unaware of the presence of the condition.

Advanced age associated with dehydration and progressive sclerosis is considered the most predisposing factor in the disease. It probably is due to a local nutritional disturbance resulting from arteriosclerosis and the stress and strain on the sclera. For this reason the term "senile hyaline scleral plaques" is preferred to more colorful names.

As far as a differential diagnosis is concerned, the author points out that scleromalacia perforans is primarily necrotic in origin, whereas scleral plaques are degenerative. Brawny scleritis is an invasion by granulation tissue and plasma cells and scar tissue is deeply pigmented, whereas scleral plaques are pale and nonpigmented.

JOSUUA ZUCKERMAN, M.D.

EAR

Hall, I. S.: Fenestration of the Labyrinth. *J. L. Otol.* Lond., 1945 60: 200.

The author reports his experiences with the fenestration operation for deafness due to otosclerosis in 71 cases during the past 6 years. The method of operation is essentially the one stage procedure developed by Lempert from the multiple stage procedure of Sourcil. A pedicle flap consisting of the thin skin of the bony posterior and superior walls of the external canal attached to the drum membrane is preserved to cover the fenestrum. The author prefers the postauricular mastoid incision to the endaural approach. The annulus tympanicus is re-

moved in the upper portion and the incus and head of the malleus is resected using care to preserve the skin flap attached to the drum in an undamaged state. A dissecting microscope is used while working on the labyrinth capsule. General anesthesia, consisting of heavy premedication and light ether is favored since immobility of the patient is desirable when using the microscope. The fenestrum is made over what is considered to be the ampulla of the horizontal canal. Electrically driven burrs of various types are used. Important points in the making of the fenestrum are considered to be the use of irrigation to remove bone dust and the care with which the endosteum and small bone chips are removed by means of small scrapers and needles. Paraffin gauze is used to hold the skin flap in position and is removed after from 5 to 7 days. Skin grafting of the cavity is sometimes carried out at the time of the first dressing by either the Thiersch or pinch method.

The results have shown a steady improvement over the 6 year period and approximately 55 per cent of operations during the past year are considered to be successful. Revision of a fenestrum which has closed is a more delicate procedure than the primary operation and entails greater risk to the membranous labyrinth. The opinion is advanced that even in cases in which the fenestrum has closed subsequent deterioration of hearing appears to be arrested as has been shown by comparison with the opposite ear. Failure to orient sounds has been noted on several occasions following the fenestration operation but vertigo has not been troublesome after the first weeks. The causes of failure which are commonly met are closure of the fenestra, advancing age and the presence of nerve deafness, infection, and technical failure.

NOSE AND SINUSES

Bernfeld, K. The Genesis of Typical and Atypical Cysts of the Nasal Floor. *J. Lar. Otol. Linc.* 1945 60 145

The term 'cyst of the nasal floor' is applied by the author to prominences of the vestibulum of the nose, situated either just in front of or behind the apertures pyriformis, extending to the lateral corner of the nasal floor and containing a liquid matter. They are rather rarely encountered. As a result of the author's experience it appears that small soft cushions of the mucous membrane with very little or no contents, are considerably more common. If, in the routine examination rhinologists did not omit the lowest, most laterally situated corner of the nasal cavity formations of this type would not be compressed nor escape attention. The author believes it may be helpful to clarify the genesis of these peculiar cystic formations.

The distinction between typical and atypical cysts has been made from a clinical and not from a genetical viewpoint. The diagnosis offers no special difficulty if the cyst is found at its typical site within the soft parts.

Palpation from underneath the upper lip with simultaneous probing will at once clarify the nature of the tumor found there. Aspiration yields a translucent yellowish fluid in which usually no cholesterol is contained.

The most important cyst in differential diagnosis is the radicular dental cyst excluded by radiography. As long as the typical or atypical cysts are small and cause no symptoms, any kind of treatment is superfluous. If however the growth of the cyst suppurates, or some other condition makes its removal imperative the procedure should be a radical one by peroral approach underneath the upper lip. The operation should be followed by cauterization which ensures a firm scar.

The total number of cases presenting typical nasal floor cysts was 3, that of atypical ones 21. 4 of the patients were children (3 girls of 8, 11 and 12 years, respectively and 1 boy of 7) 17 were adults between the ages of 18 and 38 years. The cysts occurred unilaterally in 13 cases (in 8 cases on the right) and bilaterally in 8.

JOHN F. DELANEY, M.D.

Beck, A. L. Abscess of the Nasal Septum Complicating Acute Ethmoiditis. *Arch. Otolaryng. Chic.* 1945 43 275

Abscess of the nasal septum may result from infection anywhere in the neighboring tissues, but such abscesses occur most frequently after accidental or surgical trauma. The pus may be found on one side or on both sides of the cartilaginous and bony framework. The author reports 2 cases in both of which incision on one side only was adequate.

The cartilage apparently disintegrates for fragmentation or sequestration of cartilage or bone is not always recognized at the time of and following surgical drainage. Abscess of the septum following trauma is preceded by the formation of a hematoma between the mucoperichondrium and the cartilage. Abscess following sinusitis probably is not preceded by the formation of a hematoma. There was no hematoma in either of the cases reported.

Abscess resulting from injuries accompanied by simple and compound fractures of the nasal bones must be a rare occurrence since the author has not observed it over a period of many years. Observations of persons injured in automobile accidents as they appear in the accident room of the hospital serve as the basis for this statement.

Abscess of the septum has been reported following endonasal anastomy performed through the inferior meatus. This may possibly result from instrumental trauma to the lower part of the septum in the performance of the operation.

The one infallible symptom of septal abscess is complete usually bilateral, obstruction of nasal breathing. Tenderness, pain in the nasal and orbital regions and swelling of the nose are also present. The mucosa covering the septum does not shrink when epinephrine hydrochloride and other vasoconstrictors are applied.

JOHN F. DELANEY, M.D.

MOUTH

Pignatelli, G: Solitary Neurinoma of the Tongue
(Neurinoma solitario della lingua) *Glor ital chir*
945 24

The author describes a solitary neurinoma of the tongue in a patient aged 36. The condition had been in existence for 8 months. The tongue had a normal color was moist and showed no impairment of its movements. A tumefaction was palpable at the tip of the tongue this was elastic, of rather hard consistency and was not sharply circumscribed. Pain could be provoked only by strong pressure. The lymph glands were not involved and the Wassermann, Sachs, and Meinicke reactions were negative.

Various conditions had to be considered in the differential diagnosis. Cavernous angioma is easily recognizable by its color and compressibility. A circumscribed lymphangioma is relatively hard and is usually found on the lower surface of the tongue. Ungual papillae are usually enlarged. Carcinoma or sarcoma of the tongue has a rapid evolution. Fibroma usually has a submucous location but it may be pedunculated. Lipoma, as a rule resembles a fibroma clinically but its consistency is softer. Syphilis of the tongue in the form of a gumma involves the surface of the tongue and shows a tendency toward ulceration. The blood examination confirms the diagnosis. A tuberculous granuloma as a primary manifestation of tuberculosis is very rare as a rule signs of pulmonary or intestinal tuberculosis are present. Actinomyces of the tongue shows a rapid evolution and the hard nodules gradually become soft and lead to the formation of fistulas. Hydatid cysts of the tongue are extremely rare and reach a considerable size. Glandular cysts usually have a marginal location. Congenital cysts are found at the base of the tongue and in the region of the lingual V.

The author removed the tumor under local anesthesia. Its weight was 30 gm. The histological diagnosis was neurinoma. Such tumors originate from Schwann's sheath. Several varieties of the tumor such as neurofibroma or neurinoma sarcomatodes, and neurocytoma, have been described. Parallel fibrillae cemented together with a protoplasmatic substance and nuclei located at various heights are characteristic for neurinoma. The location of the neurinoma at the tip of the tongue is very rare. No anatomic connection between the tumor and a nerve trunk could be established. Many workers consider the tumors to be hamartomas or aberrant formations of neuroblastic origin.

JOSEPH K. NARAY, M.D.

NECK

Shriver, J. W., and Cohen, M.: The Effects of Thioarsacil on the Thyroid Gland. *Ann. Int. M.*, 1945, 23 790.

Six hyperthyroid patients were treated with thioarsacil for varying periods to prepare them for

thyroidectomy. These periods were relatively short, from 9 days to a month, except in 1 instance in which the thioarsacil medication was continued for 7 months. Two of these patients had previously been prepared with iodine and subjected to a lobectomy and the histological picture at the first operation had shown the more or less typical iodine involutions effects.

At the second operation the remaining lobe in 1 of these patients exhibited the typical hyperplastic thioarsacil picture, i.e., small empty acini and pale granular cells with large pale central nuclei, while in the other case the histological picture resembled a simple colloid goiter, unaffected by the thioarsacil except in isolated hyperplastic patches where the typical thioarsacil effect was evident. In nearly every instance the gland or lobe appeared friable and vascular upon removal, no matter what the amount or character of the preparation, and the postoperative reaction was rather severe, even approaching that of the thyroid crisis. Nevertheless, in 1 patient, to whom no iodine had been administered and to whom thioarsacil had been given for only 5 days preoperatively the gland did not appear vascular or friable and the postoperative reaction was mild, and yet the microscopic picture revealed a typical thioarsacil effect. In other words, it was not always possible to correlate the clinical and the pathological pictures in this series.

In the case of the patient who had taken thioarsacil for 7 months preoperatively no mention is made of gland friability and there was no postoperative reaction, the microscopic picture showing a patchy architecture with hyperplastic areas, which was more like an untreated Graves disease than a typical thioarsacil effect. This was interwoven with lower darker celled acini and large masses of colloid, which gave the appearance that the gland was undergoing a colloid involutary process.

Although it is admitted that thioarsacil will control clinical hyperthyroidism in the patient who has undergone operation as well as in the patient who has not been subjected to it, the authors are of the opinion that iodine is still the drug of choice for preparing the thyrotoxic patient for operation. Their opinion is based upon the technical difficulties experienced by the surgeon because of the increased vascularity and friability of the gland which has been prepared with thioarsacil, the frequent stormy postoperative course, and the fact that standards have not as yet been set up to determine when the patient under thioarsacil medication is ready for operation.

Many excellent photomicrographic reproductions accompany the original article.

JOSEPH W. BRIDGES, M.D.

Bartals, E. C.: Thiobarbital in the Treatment of Hyperthyroidism. *J. Am. M. Ass.* 1945, 137 932.

Astwood has reported that diethyl thiobarbitone acid (thiobarbital) has antithyroid activity similar

to that of thiouracil. Experiments on rats showed that thiobarbital in small doses was somewhat more effective in inhibiting thyroid function and perhaps less toxic than thiouracil. However animals which received thiobarbital in larger doses were found to have fatty infiltration of the liver.

The opportune moment for the author's initial trial of thiobarbital came in October 1944, when a patient receiving thiouracil developed a fever reaction which necessitated discontinuance of treatment but further antithyroid therapy was essential before thyroidectomy. This first experience with thiobarbital revealed that this drug has unquestionable antithyroid action in human beings and that sensitivity to thiouracil does not preclude its use.

Thiobarbital has now been used at the Lahry Clinic in the treatment of 28 patients with hyperthyroidism and definite and satisfactory antithyroid response was obtained in all.

Of 9 patients in whom toxic reactions to thiouracil developed 7 tolerated thiobarbital which produced complete relief of the hyperthyroidism.

Eight of the 28 patients receiving thiobarbital, or 28 per cent, developed toxic reactions to the drug. The depressive change in the white blood cells was the only serious reaction. Two patients developed agranulocytosis. There was no death due to the drug.

The time required to control hyperthyroidism with thiobarbital was found to be the same as that with thiouracil. The antithyroid effect of thiobarbital is apparently twelve times that of thiouracil, since 0.05 gm. of thiobarbital accomplished the same result that 0.6 gm. of thiouracil accomplished. Since no side effects were observed with the smaller dose (0.05 gm.) further studies with this dose seem justified to determine its clinical effectiveness.

The anesthesia and postoperative course of patients treated with thiobarbital is similar to that of the thiouracil treated patient. The combined use of thiobarbital and iodine produced satisfactory involution of the thyroid gland.

The high percentage of reactions to thiobarbital has led to the use of thiobarbital for only those patients unable to tolerate thiouracil.

JOHN E. KIRKPATRICK, M.D.

Barr D. P., and Shorr E.: Observations on the Treatment of Graves Disease with Thiouracil. *Ann Int M.*, 1945 23 754.

Among 100 cases of thyrotoxicosis treated with thiouracil, remission was induced in 87. The drug exerted a beneficial effect on emaciation tremor hyperkinesia, and the circulatory symptoms also on the basal metabolic rate cholesterol levels the creatine defect and on the tendency of thyrotoxic patients to lose nitrogen calcium and phosphorus. Protrusion of the eyeballs was not decreased but lid spasm and lid lag were decreased or controlled.

Benefit from thiouracil was often apparent in less than 10 days, and normal conditions were usually attained within 40 days. Factors tending to retard

the rate of response were the previous use of iodine and large nodular goiters.

Of the 100 cases, 73 presented successful results in the sense that the thyrotoxicosis was maintained in remission. In 37 of the 73 cases, the drug was withdrawn for from 2 to 16½ months without relapse.

There were 3 deaths from circulatory complications, but none could be justly ascribed to the action of the drug. In 12 cases unfavorable symptoms resulted in withdrawal of the drug. Two cases of agranulocytosis were encountered.

SAMUEL KAHN, M.D.

Saltman M. F.: Carcinoma of the Larynx. Significance of the Histopathological Study of Serial Sections; Preliminary Report. *Arch Otolaryng.*, 1945 42 178.

This report concerns itself with the histological study of a block of laryngeal tissue removed by thyrotomy. The block of tissue included about 0.5 cm. of the anterior end of the right true and false cords.

Microscopic study revealed incomplete removal of the cancer *in situ* of the right true cord. Although the lesion involved almost exclusively the region of the glottic lip of the entire length of the true cord tissue there was no subglottic or ventricular extension. The presence of a greater length of cancer *in situ* anterior to the horisifying carcinoma, and of only a small amount posteriorly caused the author to conclude that the lesion grew to the anterior commissure and extended to the opposite cord.

A true picture of the laryngeal pathological changes could not be determined from the original specimen. It is believed that serial histological studies of laryngofissure specimens would prevent delay in the management of residual malignant neoplastic tissue.

NOAH D. FABRICANT, M.D.

Ivanovitch O. and Ferrari R. C.: The Treatment of Extensive Pharyngostomies following Laryngectomy (El tratamiento de los grandes faringostomas consecutivos a la laringectomia). *Boletín del Club B. Air.*, 1945 21 266.

Before the development of the modern technique extensive pharyngectomy following laryngectomy was frequently necessary because of necrosis and infections of the operative field. As a rule such infectious processes heal spontaneously or the remaining small fistulas close following minor surgical procedures. However in a certain number of cases infections or necrotic processes produce an extensive pharyngostomy especially if a large portion of the anterior aspect of the pharynx perishes. Fortunately such cases are rare.

As a rule pharyngostomies develop in patients irradiated prior to the operation because the connective tissue undergoes certain changes. Because of such changes in the surrounding tissues a repair of pharyngostomy is very difficult and disruption of the wound is the rule rather than the exception.

Fig. Second stage of the operation.

In 4 cases the authors succeeded in reconstructing the pharynx by using a tubular cervicothoracic flap. When the suture line of the tube formed a scar the circulation at the distal end of the tube was inter-

rupted by the application of an elastic forceps for gradually increasing periods of time. When in the surgeon's opinion the blood supply to the tube from the proximal end was sufficient, the lower end was severed and the so-called delayed flap was placed in proper position to cover the defect in the pharynx. The proximal end of the tubular flap was placed in the vicinity of the pharyngostomy while the lower end of the tube was placed below the clavicle and more to the side than the proximal end. To cover the defect, the distal end of the tube was turned upward and the upper portion of the tube was sectioned. The defect which was produced by formation of the tubular flap was closed with interrupted sutures.

Another rectangular flap was prepared from the opposite side of the anterior aspect of the neck, with the base at the level of the defect in the pharynx. The flap was rotated 90 degrees so that instead of pointing downward, it lay in a horizontal direction. The defect created by the change of the position of the rectangular flap was covered by a transplantation of a free flap from the subclavicular region.

Chromic catgut was used for suturing the tubular flap to the pharyngeal wall.

SURGERY OF THE NERVOUS SYSTEM

PERIPHERAL NERVES

Sunderland, S.: The Blood Supply of the Peripheral Nerves; Practical Considerations. *Arch. Neur. Psychiat. Chic.*, 1945 54 480.

Free and extensive mobilization of the nerves, often required in peripheral nerve surgery necessitates the division of many articular nervorum which bind the nerve to an accompanying arterial channel. The sacrifice of many nutrient vessels fortunately does not seriously jeopardize the nutrition of the nerve. Nerves are abundantly vascularized the anastomoses are numerous, and there is considerable overlap of supply. Experimental work has shown that the collateral circulation of a nerve is efficient even when the nerve is freed from the surrounding tissues over a considerable distance.

The author suggests the preservation of the superficial longitudinal vessels which lie in the epineurium and anastomose along the course of the nerve and advises ligation and division of the nutrient vessels some distance away from the nerve in order to preserve the vascular anastomoses. Furthermore

should a large nutrient vessel be torn or divided at the surface of the nerve it may retract into the epineurium and cause troublesome hemorrhages which result in damage to superficial nerve fasciculi and the formation of an undesirable scar

GEORGE PERREY M.D

BRAIN AND ITS COVERINGS; CRANIAL NERVES

Eaglesham D C.: Radiological Aspects of Intracranial Pneumocephalus *Brit J Radiol.*, 1945 18 335

The author states that head injuries may lead to the introduction of air into the cranial cavity and he discusses its occurrence in 23 cases observed at the Basingstoke Neurological and Plastic Surgery Hospital R.C.A.M.C from July 1942 to April, 1945

The great majority of cases occur in conjunction with fractures through the accessory air sinuses. Nontraumatic pneumocephalus may result from erosion through the paranasal sinuses of a tumor or an infective process. Although gas producing organisms may be introduced into the cranial cavity with lumps may be introduced into the cranial cavity with a resultant formation of gases these are considered essential to the discussion especially with regard to the differential diagnosis. Two examples of this condition are given in which the underlying pathological process was cerebral abscess

The radiological points favoring gas producing cerebral abscess as contrasted with other causes of pneumocephalus, are (1) the gas is remote from the usual source of pneumocephalus, i.e. the accessory sinuses (2) multiple gas pockets are close together and (3) a larger space-occupying effect than the amount of gas would suggest with a pineal shift.

Points favoring intracerebral pneumocephalus rather than gas producing abscess are (1) the presence of gas in the subarachnoid or subdural space in addition to that in the cerebrum, and (2) a rapid appearance or a rapid increase in the amount of gas seen. This, for instance may sometimes occur in traumatic pneumocephalus if the patient blows his nose

Porencephaly may also be confused with pneumocephalus after an encephalogram has been made. In porencephaly the ventricular shift, if any is to the affected side more gas is seen than was considered to have been introduced the gas pocket is at a distance from the accessory sinuses and there is persistence of the gas pocket after the air is absorbed from the ventricles and the subarachnoid space. Intracranial lipomas may give a certain radiotranslucence but less than air or gas and in the case of the latter there is not any calcification at the margins. On occasion air introduced accidentally at lumbar puncture may appear in the cranial cavity

Fig 1 Superficial blood supply of the peripheral nerve.

From the standpoint of radiological technique, stereoscopic views are always necessary to determine the extent of the shadows. An attempt should also be made radiologically to determine the source of the gas. This involves a study of the nasal and mastoid sinuses, with special reference to the cribiform plate.

All of the cases under discussion were of traumatic origin. Only 6 were due to gunshot wounds, the others being so-called closed head injuries which occurred in road accidents. The total number of patients with gunshot wounds, from which the 22 cases were culled, was 824. In some cases the exact origin of the pneumocephalus was not found. Four patients developed meningitis. When the possibility of pneumocephalus exists, radiological re-examination may be necessary from time to time.

ADRIEN VERRODORICH M.D.

Rodríguez, B., Barrios, R. R., and Oreggia, A.: A New Type of Pedunculate Syndrome. Anterior Nuclear Ophthalmoplegia and Bilateral Cerebellar Syndrome Caused by Tegmental Lesion (Un nuevo tipo de síndrome peduncular. Ophthalmoplegia internuclear anterior y síndrome cerebeloso bilateral por lesiones tegmentales) *Arch. neurol. med.*, 1945 7 353

The author reports the clinical history of a 63 year old woman who developed a vascular syndrome of the mesencephalon. The area of softening was located in the peduncular tegmentum. The clinical picture, which had a sudden onset, comprised two groups of disturbances: paralysis of the associated ocular movements of a very peculiar type (anterior internuclear ophthalmoplegia) and a bilateral cerebellar syndrome with dysarthria. In the early stages of the disease there was also a hemiplegia which receded rapidly. Several signs pointed to the involvement of the posterior longitudinal bundle. The motor inco-ordination comprised hypotonus, hypermetria, asynergia, and adiadokochesis.

The authors consider the lesion as belonging to the mesencephalic syndrome and they propose the name of oculocerebellar syndrome caused by a tegmental lesion.

JOSEPH K. NARAY M.D.

Worth, L. H.: Staphylococcal Leptomeningitis Treated with Intracisternal Penicillin. *Lancet*, Lond. 1945 249 634.

The author presents the case of a soldier who was admitted to the hospital with a diagnosis of epilepsy. A lumbar puncture was done. Ten days later the site of the puncture was found to be infected and an interapical abscess was opened. Penicillin was given intramuscularly preceding and following the operation, but no benefit was observed.

Almost a month later the patient was again operated upon. At this time an extradural abscess was found and drained through a small laminectomy opening. After a period of 4 days obvious leptomeningitis was diagnosed. Another laminectomy, with removal of all dead bone, was done. A pocketed

extradural abscess was drained. Cisternal puncture revealed cerebral fluid with 11,000 white cells and a definite staphylococcus aureus on culture. Large doses of penicillin were given by the cisternal route and the patient recovered.

The author reviews the experiences of other individuals who have used penicillin either intracisternally or cisternally. He believes that the cisternal route of administration offers advantages over the lumbar route in pyogenic meningitis, and discusses the reasons for this.

PAUL MERRITT, M.D.

Blumenfeld, C. M. and Gardner W. J.: Disseminated Oligodendroglioma. *Arch. for Psychiat.* Chic., 1945, 54: 274.

The authors present a case of oligodendroglioma which was disseminated throughout the ventricles and in the leptomeninges. The patient was examined over a period of 14 years during which he underwent a craniotomy twice. At the age of 17 he developed headaches and petit mal-like attacks and showed signs of dyspraxia with roentgenological evidence of a pituitary gland tumor. Encephalography revealed a dilatation of both lateral and the third ventricles, and at operation a thickened arachnoid was found in the region of the optic chiasm. The patient continued to have headaches and attacks, but lost many of his hypokinetic characteristics. Skull films made at the age of 24 showed calcifications in the tips of both inferior horns and in the left posterior horn of the lateral ventricles. At the age of 31 he developed convulsive seizures, ataxia, hypotonia, and had a bilateral optic nerve atrophy. He was then reoperated upon, and a cystic tumor was found posterior and superior to the optic chiasm. The patient died, and at autopsy a tumorous growth was found plastered on the walls of all the ventricles, the aqueduct of Sylvius, and the leptomeninges in various areas. The main portion of the tumor apparently originated in the hypothalamic region and had subsequently destroyed it. Histological studies proved the tumor to be an oligodendroglioma and to have undergone mucinous degeneration.

Eleven other cases reported in the literature in which an oligodendroglioma had become disseminated through the cerebrospinal fluid pathways, are discussed and furnish a basis for the opinion that oligodendrogliomas may be neither as localized nor as slow growing as is usually thought.

GEORGE PERRET, M.D.

Christensen, J. C.: Tumors of the Third Ventricle. Personal Experiences in 5 Cases. (Tumors del tercer ventrículo) *Bol. Soc. ciruj. Carab.*, 1945 4 286.

The author realizes that conclusions drawn by him from his experience in 5 cases cannot be generalized without a chance of error.

In one case the tumor of the third ventricle coexistent with an astroblastoma and tuberos

sclerosis, while in another with an isomorphous glioblastoma, a lymphangioma of the neck, and multiple nevi. An intracranial hypertension without major focal symptoms was characteristic for the entire series of 5 cases. In 3 patients paroxysmal attacks were due probably to a transitory blockade in the circulation of the cerebrospinal fluid either in the region of Monroe's foramen or in the cavity of the third ventricle.

The clinical examination revealed disturbances of the ocular motility, hypotonus, and binasal hemianopsia in all cases. Hypothalamic and mental symptoms were particularly marked in 1 case but were present to a lesser degree in other cases. In 1 patient a premature puberty and obesity appeared at an age younger than 10 years, immediately following the extirpation of the tumor. One patient developed a moderate obesity of adiposogenital character after the operation.

In 3 patients an exact diagnosis has been made on the basis of ventriculographic findings while in the remaining cases encephalography was employed.

In all cases the right transfrontal approach has been used. This type of approach is suitable for removal of all tumors of the third ventricle except those located in the posterior part.

Ventricular drainage according to Dott's technique should be employed if a considerable time elapses between ventriculography and the operation or if the surgical procedure is performed in two stages. The drainage should also be employed during and immediately after the operation.

Only 1 death could be attributed to the operation. The author considers operative results in tumors of the third ventricle as satisfactory. One year after the operation 3 patients were in a good condition while the fourth noticed a recurrence of the symptoms 3 months following the surgical intervention.

JOSEPH K. NARAY, M.D.

SPINAL CORD AND ITS COVERINGS

Rocca, E. D. and Valladares, H.: Injuries of the Spine (Traumatismos del raquis). *Arch. Soc. Cirujanos Hosp.* Santiago 1945 15 646

The authors report 85 cases of various spine injuries, reviews the mechanism of various lesions, and describes their symptomatology and treatment.

Dislocation occurs most frequently in the cervical region, mostly between the atlas and the axis or between the fifth and sixth cervical vertebrae. In the thoracic region a dislocation is observed most frequently between the eleventh and twelfth dorsal vertebrae between the latter and the first lumbar vertebra. Dislocations of the lumbar spine are rare on account of the firm fixation of the vertebrae.

Fracture-dislocation may be followed by a tear of the firm fixation of the vertebrae in the epidural space, the venous plexus located in the anterior lateral wall resulting hemorrhages on the anterior lateral or posterior aspect of the spinal cord. Blood may accumulate in the epidural, subdural or subarachnoid space and this may be followed by intraspinal

hemorrhage with a subsequent development of arachnoiditis. One of the authors' cases illustrates such a condition.

The most frequent site of fractures of the spinal apophysis is the thoracic or cervical portion of the spine.

A fracture of the vertebral arches involves the atlas or the axis in a great percentage of cases. Fractures of the vertebral body are caused nearly exclusively by an indirect trauma. In this type of fracture a medullary shock or concussion of the spinal cord is frequent and may produce a physiological section of the cord with a grave prognosis.

Fracture-dislocations of the spine are produced in a great percentage of cases by indirect trauma caused by a hyperflexion or hyperextension.

Injuries by missiles may sometimes create a picture of an anatomic section of the spine while in reality only a physiological section is present. The authors describe 1 such case in which a projectile produced an irreparable physiological section of the cord.

The degree of disintegration of the white or gray substance of the cord after a concussion depends on the intensity of the nutritional disturbances. This fact explains the appearance of medullary symptoms weeks or months after the trauma.

Medullary lesions may be situated at points distant from the site of trauma. For instance, 1 of the authors' patients sustained an injury of the dorsal region in his spine and yet the resulting myelomalacia involved the entire medullary tract. Hematomyelia or intramedullary hemorrhage, which may be produced by any type of trauma, affects the cervical portion more frequently than any other region of the spine. The original trauma may be transmitted through the column of the cerebrospinal fluid and cause hemorrhages in the gray substance at distant places.

Surgical intervention is indicated in the treatment of spinal injuries (1) if compression of the cord is demonstrated by the Queckenstedt test, stereoscopic roentgenograms, pneumospinalgrams, and myelograms, (2) if after a favorable evolution neurological symptoms of compression indicate that scar tissue is the responsible factor and (3) if symptoms of compression appear following orthopedic maneuvers.

The authors employ local anesthesia for intervention on the spine in all cases with very few exceptions. Tidal irrigation is recommended for the treatment of the cord bladder supplemented by the administration of sulfa drugs. The necessity of collaboration between orthopedic surgeon and neurologist is stressed.

JOSEPH K. NARAY, M.D.

Guthkelch A. N.: The Management of Recent Fracture Dislocations of the Cervical Spine. *Brit. M. J.*, 1945 2 880.

In fracture dislocations of the cervical spine with cord symptoms, Crotchfield tongs may be applied and the patient may then be nursed in the sitting

position. This is the main point set forth in the present article. Seven cases were treated in this way with satisfactory results. There were 4 deaths but these occurred in complete transverse lesions of the cervical cord and the lesions could be regarded as incompatible with life from the beginning.

The method is simple and can be applied anywhere. A stout post is lashed to the head of a bed and a pulley is fixed to it. The tongs are applied in a line slightly anterior to the pinna. A back rest is elevated until the patient is raised up to an angle of 60°. The tongs are weighted through the pulley with 18 pounds. Portable x-ray pictures are taken in half an hour and if there is no radiological change 4 pounds are added. X-ray pictures are taken every half hour and weight is added until the dislocation is reduced. When this happens, from 8 to 12 pounds of weight are applied and maintained for at least 3 weeks, then the weight is further reduced for 10 days and the patient is allowed up in a plaster cast.

The sitting position has several advantages: (1) gravity is used for traction; (2) the upward thrust of abdominal viscera is avoided and this is important in patients who have respiratory difficulties; and (3) the patient is able to look around, swallow properly and read. These factors promote better results than can be obtained in the usual lying position and they improve the morale of the patient.

ADRIAN VERBOOGHEM, M.D.

SYMPATHETIC NERVES

Wilson, H.: Thrombosis of the Brachial Artery Treated with Successive Cervical Sympathetic Blocks. *Am. J. Surg.* 1945 70: 255.

Blocking of the sympathetic chain is useful in the treatment of occlusive vascular disease, both of an acute and chronic nature. In thrombosis of a major vessel there is spastic contraction of the collateral channels which further decreases vascular supply to the part. Sympathetic block will relieve such spasm.

A case treated by such a procedure is presented. The patient was a 29 year old soldier whose right arm was pinned to the ground for 30 minutes as the result of an accident. He had a fracture of the left clavicle and contusions of the right chest wall and arm and of the face. The arterial pulse could be felt above the point where his arm had been pinned but not below. The right hand was cool and moist, the sensory and motor functions in the right arm were both greatly reduced. Since no hematoma was present, it was thought that the patient had a severe spasm of the right brachial artery. Three hours and twenty minutes after the accident a right cervical sympathetic block was performed with 1 per cent procaine. The results were inconclusive. Five successive blocks were performed at intervals of approximately 3 hours. The hand and arm were warmer after each block, but the effect usually disappeared in about 3 1/4 hours.

After 72 hours a weak radial pulse was felt, but this disappeared 3 days later. Sensation became

normal, but the patient had only 50 per cent use of the intrinsic hand muscles.

Four weeks after the injury the radial pulse was still absent so the diagnosis was changed to thrombosis of the brachial artery rather than spasm.

Procedures now in use in arterial injuries include ligation of a partially severed artery with its concomitant vein followed by sympathetic procaine block. Blakemore's suture method of bridging the arterial defects is occasionally used but a thrombosis or blowout may occur later. A procedure sometimes recommended is resection of part of an artery to interrupt the sympathetic supply distal to the resection. However sympathetic block is considered more complete. The author favors repeated procaine blocks rather than alcohol because of the occasional occurrence of complications such as aseptic neuritis which follows the use of the latter.

The deleterious effect of applying external heat to the affected extremity with the resultant increased oxygen demand is also stressed.

ROBERT E. GREEN, M.D.

MISCELLANEOUS

Wolf, G. A., Jr., Goodell, H., and Weiss, H. G.: Prognosis of Subarachnoid Hemorrhage. *J. Am. M. Ass.* 1945 129: 75.

In order to formulate a plan of management of patients with spontaneous subarachnoid hemorrhage the authors studied a group of 46 patients from the New York Hospital. The diagnosis of a subarachnoid hemorrhage was verified either by postmortem examination, operative visualization, or the finding of xanthochromic and bloody spinal fluid. There were no differences in sex distribution. The greatest number of cases occurred in the fifth decade, the cases being twice as common as at any other period.

Fifteen per cent of the patients had a previous history of migraine headaches, while 26 per cent had noted recurrent headaches. It was noted that the majority of patients were engaged in ordinary activity at the time of the rupture and a history of precipitating factors could not be elicited.

It was impossible to correlate the signs and symptoms with the prognosis—either immediate or late. It is of interest that many of the patients who had recovered had lost consciousness and had convulsions at the onset of the illness. Eleven postmortem examinations demonstrated aneurysms in 5 cases, but no demonstrable source of bleeding could be found in 6 of the cases.

By reviewing the current literature and their own series the authors promulgated the following percentages probabilities with the first episode of bleeding: 29 per cent of the patients entering the hospital die; 29 per cent die from recurrent bleeding between the second and fourth week, and another 5 per cent die within one year.

Based upon the previous probabilities and surgical mortality rates, an excellent management plan has been formulated.

SURGERY OF THE NERVOUS SYSTEM

1 Within the first or second week the surgical risk of craniotomy is worth while if the general condition of the patient is satisfactory bleeding has stopped and the aneurysm has been verified by arteriography. If the arteriograms are negative the patient should be confined to bed for from 4 to 6 weeks. In Dandy's surgical series arteriography was not used.

2 If after a period of one month there are persistent or residual signs or symptoms arteriography should be done. Surgery would depend upon visualization of the aneurysm, its site, and the status of the patient's general and neurological condition.

3 If the patient has no signs or symptoms directly referable to the aneurysm after the first month arteriography and surgery are optional since the surgical mortality at the present time is higher than the mortality of conservative treatment. Migraine headaches, if present, should be carefully treated during the medical regime because of the possibility of further damage to the aneurysmal wall from repeated vasodilatations.

Jack I. Wooler M.D.
Kennedy F., Somberg H. M. and Goldberg B. R.: Arachnoiditis and Paralysis following Spinal Anesthesia. *J Am Med Ass* 1945 129 664.

The authors review many of the sequelae which have been reported following spinal anesthesia, and which involve the nervous system. These symptoms comprise stiffness of the neck, involvement of the cranial nerves (second third fourth sixth seventh eighth and twelfth) impaired bladder and rectal function hemiplegia and paraplegia degeneration of the pyramidal tract, meningoencephalitis, polioencephalitis, myelitis, myelopathy radiculitis,

severe neuritis septic and aseptic meningitis, arachnoiditis, neuritis of the cauda equina and other conditions.

One case is reported in which a middle aged female developed neurological symptoms approximately 6 weeks after spinal anesthesia which had been given in connection with a pelvic operation. The patient complained of numbness and weakness of the lower extremities pain in the back, which progressed upward into the shoulder girdle, and a subsequent development of radiating pain into the hand. Incontinence of the urine and feces appeared later. Studies of the spinal fluid revealed a partial block in the canal, with increased protein. A diagnosis of arachnoiditis, secondary to spinal anesthesia, was made, and a laminectomy performed.

Destructive arachnoiditis was demonstrated at about the twelfth thoracic segment. Some improvement followed surgery.

A second patient, a male of 50 was reported as having adhesive arachnoiditis following spinal anesthesia, which was localized at the conus medullaris. Slight improvement followed surgery but a major disability resulted.

A third patient, a male of 29 was paralyzed in the lower extremities three weeks after a spinal anesthesia, and laminectomy revealed adherent arachnoiditis extending from the fourth to the tenth thoracic spinal segment. Some improvement in the condition of the legs followed but a considerable degree of disability persisted.

The authors believe that a chemotoxic effect of the anesthesia plays a definite part in the production of such symptoms and this is true particularly if there is any pre-existing disease of the nervous system.

Howard A. Brown M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Duany N P: Etiological Consideration concerning Cancer of the Breast (Consideraciones etiológicas sobre el Cáncer de la mama) *Arch C Bonas Cancer Habana*, 1945 4 121

Up to 1945 13 500 malignant tumors and 6 500 benign lesions were treated at the Radium Institute in Havana. One thousand and twenty three patients had tumors or other lesions of the breast, among them being 1 262 malignant and 463 benign tumors. Of 1 262 patients with malignant tumors, 1 248 were women, and of 463 patients with benign lesions, 457 were women. Among the benign lesions the following were observed in descending order of frequency fibroadenomas chronic mastitis or functional hyperplasia, cystic mastitis suppurative mastitis, papillomas, sebaceous cysts and gynecomastia.

Cancer of the breast was exceeded in frequency only by cancers of the uterus, oral cavity and skin.

Cancer of the breast occurred with greatest frequency in the sixth decade of life to be followed by the fourth fifth and eighth decades in which cancer occurred with approximately equal frequency. Then in descending order of frequency were the seventh, ninth, tenth, third, and second decades, other ages accounting only for a very small number of cases.

Seventy-eight per cent of the patients with cancer of the breast belonged to the white race 10 per cent were negroes, and 12 per cent were of mixed race. The entire population consists of 74.4 per cent of white people and 25.6 per cent of negroes and those of mixed blood.

In the author's material cancer of the breast occurred three times as often in multiparae as in nulliparae.

The relation between trauma and the development of sarcoma can be established much easier than that between trauma and the development of cancer.

In the author's material cancer was found in the patient's mother or father in only 1.1 per cent of the total. Apparently such antecedents are of no great importance.

The term mastitis, used by older pathologists apparently means nothing but hyperplasia gradually developing in women over 35 years of age. The term "mastitis" should be applied only to an inflammatory process. Evidence of such acute and chronic lesions was found by the author in only a small percentage of his material.

He concludes that apparently no relations of any importance exist between inflammatory processes and cancer of the breast.

A hereditary tendency toward cancer could not be definitely confirmed by the author's observations.

JOSEPH K. NARAT, M.D.

TRACHEA, LUNGS, AND PLEURA

Crafoord C., and Lindgren, A. G. H.: Mucous and Salivary Gland Tumors in the Bronchi and Trachea. *Acta chir scand*, 1945 93 421.

The authors' material of so-called bronchogenic adenomas comprises 14 cases, the tumors being located in the bronchi in 9 cases and to the trachea in 5 cases.

These adenomas were demonstrated to belong to the group of mucous and salivary gland tumors, and like such tumors in other locations, they may be classified as benign semimalignant (Klason, Rostvall) and malignant. Of this series, 7 were benign, 5 semimalignant, and 2 malignant.

The classification of the tumors in question as mucous and salivary gland tumors explains both the clinical course of the cases and the biological character of the tumors.

Tumors of this kind are generally benign, but sometimes they display signs of a certain local biological malignancy by producing inflammation and destruction and by causing metastases. However, the degree of malignancy generally appears to be low.

The authors believe that these tumors should be radically removed, if technically possible, as it is difficult to determine their malignancy or semimalignancy histologically in excised material. It is a known fact that so-called semimalignant mucous and salivary gland tumors can occasionally change to decidedly malignant tumors in the course of time.

Abbott, O. A., and De Oliveira, H. R.: Spontaneous Pneumothoraces Occurring in Patients Undergoing Peroral Endoscopy. *J. Thorac. Surg.* 1945 14 453.

There are many common complications of bronchoscopy such as the danger of direct injury to the bronchus and underlying vessels, the danger arising from local or general anesthesia, and the occurrence of subglottic edema. All too little attention has been paid to pneumothorax as a bronchoscopic hazard.

Kahler, Soulas, and Benjamin have reported instances of pneumothorax or subcutaneous emphysema following trauma to the bronchial tree which occurred while attempting the removal of foreign bodies. Here the mechanism of the leakage of air into the mediastinum is evident.

The authors are chiefly interested in the occurrence of pneumothorax following diagnostic peroral endoscopic examination. Examination of the literature revealed only 1 case similar to the cases reported in the authors' series.

Spontaneous pneumothorax most commonly is attributed to the rupture of a subpleural (subcutaneous) focus. Other causes are pneumococci, pulmonary gangrene, bronchiectasis, lung abscess, foreign body

SURGERY OF THE THORAX

emphysema tumor congenital cysts, and pulmonary emphysema. Penetrating injuries to the chest wall or injury from within the bronchial tree by sharp objects or instruments obviously may produce pneumothorax.

Pneumothorax following bronchoscopy may be due to direct injury to the visceral pleura by the bronchoscopist. However as these patients have diseased lungs spontaneous pneumothorax may occur without endoscopic examination. Thoracic surgeons who use the bronchoscope on patients will most likely make periodic fluoroscopic examinations and discover unsuspected pneumothoraces. A majority of cases have sufficient pleural adhesions to minimize symptoms complicating the pneumothorax. This, unfortunately does not always occur and the complication may lead to dire results unless one is familiar with it.

The incidence of this complication is uncertain since routine fluoroscopies are not done following bronchoscopy. The authors 4 cases of pneumothorax following bronchoscopy occurred during a period of 12 months during which 537 bronchoscopic examinations were made on a surgical chest service for diagnosis or therapy. No bronchoscopic examinations were carried out for the removal of foreign bodies.

The authors present 6 case reports. In none of the patients was there any evidence of direct injury to the major bronchi. In 2 cases the pneumothoraces occurring coincident to bronchoscopy were asymptomatic and were accidentally discovered by fluoroscopy. In spite of the fact that both patients had suppurative lung disease, no empyema occurred. In 1 case the pneumothorax probably was due to the rupture of an emphysematous bleb since these are occasionally associated with patchy atelectasis in children. A similar etiology was suspected in an other case.

In the third case a pyopneumothorax developed secondary to rupture of a weakened necrotic area of a peripheral abscess. This is a spontaneous phenomenon which is likely to occur in these cases. It is a hazard of the coughing paroxysm subsequent to endoscopic manipulation rather than a complication of the procedure.

The fourth patient had advanced tuberculosis and far advanced pulmonary emphysema. Either or both etiological agents may have played a role during the postbronchoscopic coughing paroxysms.

The fifth patient had no postbronchoscopic pneumothorax, but died as a result of bronchoscopy and the associated coughing attacks. Possibly the explanation may be that in pulmonary emphysema, compression stenosis of the trachea may account for dyspnea with coughing attacks however the true explanation remains a mystery.

The sixth case described is rare and may be used to support Hammen's theory that spontaneous mediastinal emphysema may advance to the production of a pneumothorax. Two explanations have

stilled hands of connective tissue to the pleural surface of the lung which ruptures (2) the air in the mediastinum achieves sufficient tension to rupture the thin mediastinal wall into the pleural cavity. Most evidence seems to support the second route as the most likely.

Pneumothorax has many serious dangers attendant upon it and a consciousness of this complication in association with peroral endoscopy should prove lifesaving in some instances.

ROBERT R. BIGELOW, M.D.

Melick, D. W. and Spooner, M.: Experimental Hemothorax. *J. Thorac. Surg.* 1945 14 461

Experimental evidence is presented in support of the theory that blood coagulates normally in the pleural cavity. Blood introduced into the pleural cavities of dogs coagulates normally. Both the liquid portion of the blood and the clot are readily absorbed. The liquid portion disappears within from 10 to 14 days and the clot decreases in size to such an extent that it may be overlooked. After 2 weeks have elapsed little evidence remains to show that blood had previously been present in the pleural cavity.

The red cells are not laked immediately after introduction into the pleural cavity. They are recognizable after 5 days, although some are fragmented at that time. The fragmented erythrocytes are taken up by the macrophages, and appear as hemosiderin within the phagocyte.

The liquid portion of the blood will not clot, as it consists only of serum and cells, and will remain incoagulable indefinitely. Fibrinogen added to this liquid portion however will bring about coagulation. The pleura itself does not elaborate an anti coagulant.

SAMUEL KAHN, M.D.

Burford, T. H., and Burbank, B.: Traumatic Wet Lung. *J. Thorac. Surg.* 1945 14 415

In all wounds of the chest the lung tissue reacts to a greater or lesser degree according to the severity and type of the lesion, to produce more than its normal amount of interstitial and intra-alveolar fluid. The bronchopulmonary tree not only has more fluid of which to rid itself but also becomes less capable of doing this. The result of these factors may be called the "wet lung" of trauma. On the degree of "wetness" and on its recognition and treatment depends the outcome in many cases.

The primary phase of this syndrome finds the patient apprehensive. Dyspnea, accompanied by paroxysms of painful cough, is present. The cough however does not serve to empty the bronchopulmonary segments. On examination there is found restriction of motion of the involved side with diminished breath sounds. The outstanding feature is the presence of rales bilaterally but more marked on the affected side. In some instances the patient appears to be having a typical attack of bronchial asthma. In many cases the condition resembles non-traumatic pulmonary edema.

Recognition of the presence of "wet lung" should not detract from the importance of other lesions which may be present. The necessity for the proper treatment of these lesions must be stressed.

In treating "wet lung" the aim must be to control the production of moisture and to promote adequate bronchial drainage. Since pain originating in the traumatized thoracic cage structures, is the most important factor in the development of the unfavorable cycle of events, and since the pain interferes seriously with an effective cough mechanism the pain must first be combated. The use of morphine and adhesive strapping is physiologically unsound and ineffective. The use of procaine injections, either at the site of injury by intercostal nerve block, or by thoracic paravertebral sympathetic nerve block gives gratifying results which are often dramatic.

While the abolition of pain and the reinstitution of a painless, effective cough mechanism are essential, other forms of therapy are often also necessary. The bronchopulmonary tree may be flooded. The secretions should be mechanically evacuated by tracheobronchial catheter aspiration. In some cases, atropine given intravenously may be of value. In the more resistant cases, oxygen, delivered at a positive pressure of from 6 to 8 cm. of water is of benefit.

Traumatic "wet lung" must be differentiated from bronchial asthma, pulmonary edema of cardiac origin, pulmonary edema seen in peripheral vascular failure, and from blast lung. SAMUEL KAHN M.D.

McDonald, J. R., Moersch, H. J., and Tinney W. S.: Cylindroma of the Bronchus. *J. Thorac. Surg.* 945 14 445

Six cases of cylindroma of the lung are reported. The clinical course was remarkably similar to that of adenoma of the bronchus, with the exception that in 1 case the neoplasm involved the trachea. The bronchoscopic appearance of the tumor also was similar to that of adenoma of the lung. The lung which is the seat of a cylindroma grossly resembles that in which an adenoma is found in that bronchiectasis and lung abscess are common sequelae to the long-standing obstruction produced by the tumor. Cylindroma histologically presents a different appearance from that of adenoma of the bronchus and seems to be more closely allied to mixed tumors

Valle, A. R., and White M. L., Jr.: Penicillin in Pulmonary Resection. *J. Thorac. Surg.* 945 14 437

Pulmonary resection in recent years has become a refined surgical operation with a mortality which is comparable to that of the major abdominal procedures. This development is due to (1) increased knowledge of thoracic physiology and pathology (2) progress in anesthesia, (3) increased knowledge of shock and fluid and blood replacement, (4) increased knowledge of the surgical anatomy of the lungs, and (5) developments in chemotherapy

Chemotherapy, the most recent development, has contributed to the control of infection of the pneumonia, pleura, and chest wall. For the last 5 years the sulfonamides have controlled postoperative pneumonias and diminished pleural infections. The discovery of penicillin opens a new field in the control of postoperative pleural infections. White, Nicholson, and Stevenson, and D. Abreu, Litchfield, and Scott have all demonstrated the protective value of penicillin in controlling pleural infection. D. Abreu and his coworkers have shown that penicillin instilled in the pleural cavity is retained for as long as 3 days while, conversely its passage from the blood stream into the pleural cavity is slight. In a recent article Blades reported that the incidence of empyema in a penicillin-protected and control series was about the same.

In the present article, the authors compare its course and results in patients with pulmonary resection who were treated with and without the administration of penicillin. The authors discuss their technique of pulmonary resection and stress the problem of drainage and the method of using the penicillin.

Preoperatively for 2 or 3 days, 10,000 units of penicillin were given intramuscularly every 3 hours. This was usually continued postoperatively for 3 or 4 days, and over a period of 7 days in heavily contaminated cases. Fifty thousand units of penicillin in 10 c.c. of saline were injected into the pleural space through a catheter at the completion of the operation. For 6 or 7 days after operation, 50,000 units of penicillin were injected daily into the pleural space through the catheter or (after removal of the catheter) following thoracostomy.

This series consisted of 48 consecutive pulmonary resections carried out during a period of 31 months, the first 28 without penicillin, and the last 20 with penicillin therapy as described. The two groups were roughly similar as to diagnosis and operative procedure.

In group 1 (without penicillin) there were 25 lobectomies and 3 pneumonectomies. Of the lobectomies, 15 were for bronchiectasis, 4 for tuberculosis, 3 for lung abscess, and 3 for cystic disease. Two of the pneumonectomies were for carcinoma and 1 for sarcoma. Nineteen of the 23 cases (83%) involved some division of pulmonary tissue and were considered as contaminated.

In group 2 there were 15 lobectomies and 5 pneumonectomies. Of the pneumonectomies, 3 were for bronchiectasis, 1 for carcinoma, and 1 for tuberculosis. Of the 15 lobectomies, 11 were for bronchiectasis, 2 for tuberculosis, 1 for pulmonary cyst, and 1 for lung abscess. In 13 cases (86%) there was division of pulmonary tissue with grossly contaminated pleural spaces.

In group 1, two of the pneumonectomies were uncomplicated, the third patient developed a bronchial fistula with a fatal empyema. Bronchial fistulas developed in 10, or 40 per cent, of the patients who had undergone lobectomy. One patient

SURGERY OF THE THORAX

with pneumonectomy and all patients with lobectomy developed empyema. Tubal drainage for an average of 12 weeks was required.

Of the pneumonectomies in group 2 all patients had uncomplicated recoveries. Of the lobectomies, none of the patients developed an empyema. fistula and only 1 patient developed an empyema.

Fourteen per cent, or 4, of the patients in group 1 developed chest wall infections while no case in group 2 was so complicated.

The patients in group 2 showed a marked decrease in days of hospitalization and an earlier day of rising after operation. The average febrile reaction was slightly less than that of the patients in group 1.

Aspiration of the chest in group 2 patients on the first postoperative day yielded from 400 to 500 c.c. of fluid. The quantity decreased rapidly and thoracentesis was seldom needed after the seventh day. Except for empyema in 1 case all cultures were negative. This was in marked contrast to the common empyemas in group 1.

Three of the patients in group 1 died—one of these (who had had a pneumonectomy) from an empyema due to a bronchial fistula, another as the result of a tuberculous pneumonia and the third patient, from a suppurative pericarditis secondary to a small basal empyema. One patient in group 2 died as the result of an extensive tuberculous spread.

The authors discuss in detail the single case of empyema in group 2 which represents a cure of empyema with penicillin, and without surgical drainage. An interesting case of lobectomy (group 2) in which pus was spilled into the pleural cavity is also discussed. Here in spite of extensive gross contamination no pleural or chest wall infection developed.

The authors attempt to show the advantage of using penicillin intrapleurally and intramuscularly in pulmonary resection without drainage of the space. They believe that the evidence points to prophylaxis of the pleural space from infection by penicillin. Blades reported that 11 of 29 patients who were treated with penicillin developed empyema. The difference between these figures and the authors' figure of 1 case in 20 probably can be explained by the fact that the authors do not drain the pleural space even for a few days therefore a high concentration of penicillin can be maintained by daily injections.

Successful bronchial closure is important, but it is not the only factor to be considered in the prevention of empyema. The authors believe that an empyema may contribute to the formation of a bronchial fistula. By maintaining pleural aseptals and maximal re-expansion of the remaining pulmonary tissue, the chances of bronchial fistula are lessened.

The clamped-off catheter of aspirating fluid during the 48 hours when the patient is most uncomfortable. Its advantages are that the penicillin concentration intrapleurally is kept as high as possible. Secondly it facilitates the re-expansion of the

remaining lung by the negative intrapleural pressures induced and maintained by fluid aspiration. Should an empyema develop it is apt to be small, and recovery rapid.

A striking demonstration of the value of penicillin is shown in the heavily contaminated cases in which lung tissue has been divided in the open pleura. Finally, the patient's postoperative course with penicillin, is smoother there is earlier rising and a shorter hospital stay. In a larger series of cases the mortality should be consistently lower since the dangers of putrid empyema and bronchial fistula are decreased with the use of penicillin.

ROBERT R. BICKLOW M.D.

Adams, W. E. Thornton T. F. Jr. and Carlton L. M. Jr.: The Use of Blood Plasma for Filling the Pleural Space following Total Pneumonectomy. *Ann. Surg.* 1945 122 905

In view of the results of experiments on a variety of animals Adams and his associates found it worth while to test the influence of filling the pleural space with plasma following total pneumonectomy in man. Eighteen patients received such treatment and 10 additional patients used as controls, received no plasma. The usual method of management consisted in the determination of the red cell count, hemoglobin value and plasma protein prior to operation. At the time of surgery between 500 c.c. and 600 c.c. of plasma were introduced into the pleural cavity at the closure of the thoracic wall and 200,000 units of penicillin were placed in the pleural space of 9 of the 18 patients.

Between 1 and 3 days after operation, following chest fluoroscopy the remainder of the residual air was removed and replaced with plasma usually amounting to from 200 to 400 cubic centimeters.

From the data presented and also from studies as yet unpublished, it was evident that the greatest drop in red cell count, hemoglobin and hematocrit readings occurred between the third and fifth day after surgery. Following this there was a slow return to normal but in most instances the preoperative plasma protein level had not been reached by the end of the 2 weeks following operation.

The lowering of blood plasma proteins was also greatest usually by the third to the fifth day but the fall did not always parallel that of the hemoglobin. In some patients the red cell count and hemoglobin remained at very nearly the preoperative level although the plasma proteins fell. When the proteins were lowered to from 1 to 2.5 gm. per cent they usually had not returned to the preoperative level by the end of 2 weeks following operation.

The average fall for 14 patients who received plasma in the pleural space was 0.90 gm. per cent. In contrast to this, the average fall for the control group was 1.48 gm. per cent or almost twice that of the treated patients. It was seen moreover that a high percentage of the treated patients had only a slight lowering of the plasma proteins and maintained a higher postoperative level than the controls.

The incidence of serious complications and the mortality rate were almost twice as great in the control group as in the group which received plasma in the pleural space following resection of the lung.

It is thought that although the series of patients is not large, the discrepancy between the two groups is significant.

A striking difference in the incidence of post operative empyema and bronchial fistula was seen between the methods of bronchial closures. Of the 12 patients in whom a s row suture technique was employed 4 developed an empyema, 3 of whom had a bronchial pleural fistula. In contrast with this, none of the 16 patients whose bronchial stump was closed by a single row suture technique developed either an empyema or fistula following operation.

STEPHEN A. ZIEGLER, M.D.

Delmas, J. E.: The Operative Treatment of Fistulous Empyemas following Pneumothorax (*Traitements opératoire de los empiemas fistulados postpneumotóraxicos*). *Rev. esp. cir. torac. bronq.* 1945 3: 270.

The author discusses the operative treatment of cutaneous fistulas complicating a spontaneous or therapeutic pneumothorax. He performed 7 thoracotomies on account of chronic empyema following pneumothorax. These cases did not include empyema following pleurisy or traumas of the chest. His material belongs to Hedblom's groups 2 and 4. Usually in such cases an encapsulated pleural cavity is found with the mediastinum and the corresponding lung retracted the pleura has lost its ability to expand, the ribs are practically in contact with one another and there is a corresponding deformity of the chest. Multiple fistulas with surrounding cutaneous ulcerations are present. As a rule the condition is complicated by myocardial degeneration and visceral amyloidosis.

As to the treatment, extrapleural thoracoplasty cannot always be carried out. To replace thoracotomy Kirschner suggested intrapleural methods after an anterior resection of the second and third ribs. In selected cases pleurectomy may be performed.

Schede's extensive thoracotomy is a very serious intervention which should be performed in stages. McDonald suggested a combination of intrapleural and extrapleural methods. Sauerbruch performs a paravertebral columnar thoracoplasty on the first to the ninth ribs in the first stage, in the second stage he removes completely the tenth and eleventh ribs and obliterates the empyema and in the third stage he performs a parasternal resection of the first to the eighth ribs.

The author modified Braun's procedure, which in turn is an improvement of the original Schede method. It is advisable to make the intervals between the various stages of the operation as short as possible to prevent degeneration of the thoracic wall. As a rule in the first stage a superior paravertebral resection of from 5 to 7 ribs is performed. In the

second stage a paravertebral columnar resection of the lower ribs is done and the intercostal spaces are resected. In the third stage the pleurectomy is done. Sometimes the first stage consists only of an anterior resection of the first to third ribs with corresponding cartilages. In the second stage a paravertebral resection of the first to fifth ribs is performed and the intercostal spaces are resected. In the third stage a paravertebral resection of the sixth to the eleventh rib is performed and the fourth stage consists of pleurectomy. Great care is taken to leave the drainage tube in place during the intervention because the alteration of the thoracic wall after rib resections makes the introduction of a drainage tube into the old fistula very difficult. The intervention can be done under local anesthesia supplemented by a costopleural bloc.

The author concludes from his studies that a fistulous empyema without retention of pus in a patient in a good general condition can be treated by drainage and aspiration. A residual cavity requires a limited pleurectomy. A rigid cavity with considerable pachypleuritis should be treated by pleurectomy according to the described technique. Pleurectomy should be preceded by an interruption of the intercostal nerves. If the cavity is small, a one stage limited pleurectomy should be performed.

JOSEPH K. HART, M.D.

HEART AND PERICARDIUM

Watts, T. D., and Toome, E. G.: Successful Removal of Foreign Bodies within the Pericardium. *Surgery* 1945 18: 685.

Inasmuch as the proper management of foreign bodies within the pericardial sac has remained indefinite the authors report a cases in which the patients were treated by successful surgical removal. One case of successful surgical removal has been reported previously.

It is not intended to recommend, from the experience with these 2 cases and the 1 previously reported, that all foreign bodies of the pericardium should be treated surgically. For the most part the question of surgical intervention lies with the clinical appraisal of each individual case by both the clinician and surgeon. The patient's symptoms, the objective evidence of pericardial or myocardial changes, and the possibility of future complications are to be balanced against the operative risk. Each of these points of evaluation are at present subject to wide variations in interpretation, and a clear cause-and-effect relationship of the symptoms, the signs, the pathology encountered, and the possible complications is lacking in most reports.

The presence of extensive and dense fibrous within the pericardium has been an outstanding finding in each case and probably is the underlying basis for the subjective complaints and the abnormal objective findings noted. As a result of this observation and especially as a result of the authors' experience with 1 patient the optimum time for re-

gical removal would seem to be as soon as the circulatory function becomes stable and the patient's general condition permits.

There were abnormal electrocardiographic findings in the case previously reported and in each of the cases in this report.

In the former these findings were interpreted as indicating myocardial damage because of the depth of the inversion of the T waves in Lead 4 and the failure of the patient to show improvement in the weeks of observation following operation. In the latter cases of this report the electrocardiographic changes were thought to be due to pericardial damage. In both instances the electrocardiogram showed a return to the normal configuration following the operation.

In addition to the immediate consequences of a foreign body within the pericardium subsequent developments of a serious nature may result. There is always the danger of infection arising at the local site of any foreign body particularly when organic material such as clothing is present, as is often the case in penetrating shell fragment and bullet wounds. The adjacent vital structures such as the heart chambers or the great vessels may be eroded or penetrated with serious or disastrous results.

JOHN E. KIRKPATRICK, M.D.

Max, F. H., Awad, S., and Pedraza, C.: Pericarditis (Pericarditis). *Rev Med Chile* 1945 73 833

Of 42 cases of pericarditis observed by the authors 20 were of rheumatic origin, 7 were tuberculous, 6 the cause could not be established and 2 followed septicemia, 2 anemia, 3 secondary pneumococcus infection, 1 primary pneumococcus infection, 20 cases were uremia and pneumococcus infection, 20 cases were acute and 13 chronic.

Of 20 cases of rheumatic pericarditis, 4 developed in the course of the first attack. Of the 20 cases 15 presented valvular lesions. In 11 patients an exudative pericarditis was diagnosed, in 4 a dry type, and in 1 patient a symphysis while in the remaining 4 cases the exact diagnosis could be established only at autopsy. The character of the exudate by autopsy in 15 cases by paracentesis in 2 patients by autopsy in 1 and by clinical and x ray examinations in 7. Of the first 4 cases, 2 had a hemorrhagic serofibrinous exudate, 1 case had a hemorrhage and 1 a sero-exudate, 1 case had a hemorrhage and 1 a sero-exudate.

Of 7 tuberculous cases, 6 had signs of polyserositis, 5 of them had an exudative pericarditis, and 1 had an adhesive form while the seventh case presented a partial constrictive chronic pericarditis.

Both uremic cases had a serofibrinous exudate. Of 3 patients with septicemia, 1 had a hemorrhagic serofibrinous and the other a fibrinopurulent exudate.

Of the 4 patients with pneumococcus, 1 patient had a primary form while 3 patients had had pneumonia. One patient had a fibrinopurulent exudate, the other a purulent, the third a serofibrinous, and the fourth a fibrinous exudate.

Of 29 patients with an acute pericarditis only 1 patient presented a picture of tamponade of the heart.

Of 13 patients with a chronic pericarditis, 3 showed signs of a chronic compression.

An elevation of the sedimentation rate was noticed in the majority of patients with the rheumatic form. They had anemia, neutrophil leucocytosis, and a deviation of the blood picture to the left.

The ages of the patients with the rheumatic form ranged from 13 to 40 years, that of patients with the tuberculous type from 11 to 25 years, while the age of those with the pneumococcal form ranged from 29 to 65 years.

Of 15 patients with pericarditis 8 showed electrocardiographic signs of an acute type, 6 those of a chronic type, and one patient had no pathological signs whatsoever.

Clinically the condition was characterized by the following signs: (1) cyanosis, (2) dyspnea, (3) venous hypertension, (4) arterial hypotension, (5) venous congestion of the neck and an inspiratory enlargement of the jugular veins, (6) edema of the lower extremities and in the receding position also of the chest and upper extremities, (7) paradoxical weak pulse and tachycardia as a compensatory phenomenon, (8) hepatomegaly and splenomegaly, (9) ascites, and (10) cardiac manifestations such as intensified third sound to the left of the sternum, small cardiac dullness, diastolic impulse, systolic depression and absence of the apical impulse.

Röntgenological findings are important in exudative but not in dry pericarditis.

JOSEPH K. NABAT, M.D.

Ivanovitch, O. and Martians, L. H.: Treatment of the Encased Heart. Chronic Constrictive Pericarditis (Tratamiento del corazón aprisionado). *La pericarditis crónica constrictiva*. *Boletín de la A. G. Cir.* B. Air, 1945 31 339.

The authors operated on 8 patients with chronic constrictive pericarditis. Three patients were cured, 1 patient showed marked improvement in his condition, 2 patients showed temporary improvement but death occurred later on and 2 patients succumbed to the operation.

An intervention should not be undertaken until the primary condition has passed its acute stage. This statement holds true particularly in cases of tuberculosis of the pericardium. Surgical intervention undertaken to free the heart during the evolutionary stage of tuberculosis has proved unsuccessful and caused death. The patient developed a bacillary meningitis and died from it. Tuberculous lesions were found in the extirpated pericardium. Patients with a marked passive cardiac deficiency should not be subjected to an operation.

Before the operation an attempt should be made to improve the patient's condition and the cardiac efficiency. Furthermore, serous effusions should be evacuated to prevent if possible a new formation of adhesions.

Blood transfusions should be given before the operation if necessary. Either local or general anesthesia, with cyclopropane or ether given through a tracheal tube can be used. Any approach with which the surgeon is familiar may be used. Extirpation of the pericardium should be as ample as possible. Total pericardectomy is not always possible on account of firm adhesions which are likely to exist in certain zones between the heart and the pericardium. In such cases which are relatively frequent a partial pericardectomy must be performed. Experience has shown that many patients have fully recovered after partial extirpation of the pericardium.

The authors obtained a cure in 37 per cent of their material. This figure compares favorably with that of other authors who show cures in from 22 to 36.6 per cent of their cases.

JOSEPH K. NARAY, M.D.

Shallard B.: Patent Ductus Arteriosus. *Med. J. Australia* 945 : 353.

The prognosis in patients with patent ductus arteriosus is poor apart from surgical treatment. Shallard reports in detail the cases of 14 patients on whom operations were performed. Four succumbed to operation: 3 from hemorrhage and 3 from other causes and 1 died from subsequent infective endocarditis.

In discussing the diagnosis it was thought that there is not one clinical sign which alone can be depended upon as being constant. The murmur described as continuous machinery water wheel, train-in-tunnel may not always be found. In 2 of the patients the murmur at the initial examination was limited strictly to systole. The diastolic component developed during a period of observation of 6 months in one patient and during a period of 3 years in another.

X-ray pictures are invaluable in diagnosis, but are not pathognomonic. Dilatation of the pulmonary artery was present in only two-thirds of the cases. Left ventricular hypertrophy was found radiologically and a deviation occurred in the electrocardiograms in 4 cases. Significant changes in the S-T intervals in two readings were observed.

Pallor, a clinical sign not hitherto described, is considered important, and anginal pain on effort was reported by 2 adult patients. These symptoms are unusual in patent ductus arteriosus.

STEPHEN A. ZIEGLER, M.D.

Paton C. N.: Anesthesia in Cases of Ligation of Patent Ductus Arteriosus. *Med. J. Australia* 945 : 361.

Basal narcosis with avertin, followed by inhalation anesthesia with cyclopropane was found to be a satisfactory form of anesthesia in a series of cases of ligation of a patent ductus arteriosus.

Cyclopropane was selected because of its non-toxic and nonlimiting features, the shallow type of respiration it produces, the ease with which con-

trolled respiration can be instituted, the low concentration of oxygen in which it is administered, and its reversibility. A standard McKesson machine was used which facilitated the application of accurately measured positive pressure.

Endotracheal intubation was an added advantage because a minimum of disturbance of cardiac and respiratory function was experienced. Complications either during or after operation were surprisingly few.

STEPHEN A. ZIEGLER, M.D.

Edye, B. T.: The Surgical Treatment of Patent Ductus Arteriosus. *Med. J. Australia*, 1905, 365.

Edye describes the procedure he employs in the surgical treatment of patent ductus arteriosus. He approaches the pathological condition through a planned space, verified by skiagrams to be opposite the second left intercostal area. An oblique incision over this intercostal space was made, coursing upwards and outwards in the direction of the fibres of the pectoralis major muscle from the margin of the sternum to the line of the anterior axillary fold. The muscle was split and not divided. In the older patients a curved incision was made with the convexity upwards to avoid the mammary tissue. The pleural cavity was entered by incision of the intercostal muscles and pleura, and the cartilage of the second and third ribs were divided. The lateral mammary artery was sometimes divided between ligatures, but at other times the incision stopped short of it. If it was injured it caused troublesome hemorrhage and delay. A rib spreader was inserted over gauze sponges and the wound was widely opened. A light gauze pack was inserted to prevent the collapsed lung. The diagnosis was confirmed by the characteristic thrill detected on palpation at or near the site of the ductus. Usually the anatomical structures including the phrenic and vagus nerves and the left subclavian artery were clearly visible. The ductus joins the aortic arch at or just beyond the level of the origin of the latter. This preliminary examination completed the mediastinal pleura was divided vertically between the 2 nerves. The posterior leaf was raised to bring into view the recurrent nerve which hooks around the aorta immediately to the left of the ductus, and is a most important guide to the latter. The ductus was located by making pressure over the interval between the aortic arch and the pulmonary artery at various points until the thrill was obliterated.

The dissection of the ductus was a tedious process, fraught with considerable anxiety for its end was apt to be delicate and easily torn. The interval between the aortic arch and the pulmonary artery was gently widened by blunt dissection with key curved forceps a little distance to the right of the ductus, and the process was repeated closer to the ductus until that aspect was freed. A smaller dissection was carried out on the opposite side, the left recurrent laryngeal nerve being used as a guide. The forceps was then insinuated posteriorly so as gradually

ally to open the interval between the ductus and the left bronchus behind. It was during this stage of the dissection that the ductus was apt to be torn. The maneuver was assisted by counter pressure with the left index finger in the interval between the aortic arch and the pulmonary artery to the right of the ductus. Narrow malleable copper retractors were a useful aid in the exposure of the ductus.

The next step was the passage of a MacCormick dissector behind the ductus aided as before by counter pressure with the left index finger care had to be taken not to catch the posterior aspect of the ductus with the instrument. When the dissector had been passed no attempt was made as a rule to free the ductus any further posteriorly, but the dissector now loaded with number 8 silk, was passed and the ligature was drawn through. The ligature slipped through with greater ease when the dissector was *in situ*. A second ligature was compressed digitally about this stage the ductus was compressed digitally and the effect on the circulation was noted. If after 1 or 2 minutes there were no untoward effects, the ligatures were carefully but firmly tied. By palpation and by auscultation with a sterilized stethoscope, it was determined that the thrill and murmur had disappeared. The incision in the mediastinal pleura was sutured as well as possible. Any blood was aspirated from the pleural cavity and the chest wall was closed in layers. The divided costal cartilages sometimes were and sometimes were not sutured with catgut. The ribs were drawn together with sharp hooks during the closure of the pleural cavity and the lung was encouraged to expand by the anesthetist and also by suction of air from the pleural cavity before final closure. No drainage was provided convalescence was usually uneventful, and only on occasion was it necessary to aspirate pleural fluid. The blood transfusion was continued slowly throughout the operation.

It must be remembered that when cardiac efficiency has been impaired it is possible the introduction of a large amount of blood may be detrimental.

STEPHEN A. ZEEMAN, M.D.

Groom, R. E.: Surgical Relief for Tracheal Obstruction from a Vascular Ring. *N. England J. M.* 1945 233 386.

In an infant with symptoms of tracheal obstruction (crowing inspiration, dyspnea, intercostal and suprasternal respiratory retraction) there developed attacks of superimposed tracheitis, for which the patient was hospitalized on 4 different occasions. Fluoroscopic studies made after the patient had a swallow of barium showed what appeared to be a mass lying behind the esophagus, opposite the third and fourth thoracic vertebra, with the esophagus itself pushed forward and narrowed in both the anteroposterior and lateral views. Instillation of the lipiodol showed a fairly marked narrowing of the trachea just above its bifurcation at a level corresponding with the previously described esophageal deformity. This narrowing was apparent in the

Fig 1 Arrangements of the great vessels as found at operation. The ascending aorta bifurcates into two branches one passes behind the esophagus and the other arches in front of the trachea. The two branches join to form the descending aorta. Within the vascular ring the esophagus and trachea are compressed. AA—ascending aorta; E—esophagus; IA—innominate artery; J—junction of the two aortic arches; LA—ligamentum arteriosum; LCCA—left common carotid artery; LSA—left subclavian artery; PA—pulmonary artery and T—trachea.

anteroposterior view and was particularly noticeable in the lateral film.

Operation was then performed at once, although the patient was in a precarious state at the time. Under cyclopropane anesthesia the chest was opened through a left anterolateral incision and the pleural cavity was entered through the third interspace with separation of the third and fourth costal cartilages. The left pleural cavity was traversed to reach the mediastinal structures. When the mediastinal pleura was opened the aorta was seen to divide into two vessels which enclosed and greatly constricted the esophagus and trachea and then joined to form the descending aorta. The left common carotid and left subclavian arteries came off the smaller anterior segment of the ring in the usual manner for the aortic arch and the much larger posterior segment gave issue to the innominate artery.

First the ligamentum arteriosum was divided between silk ligatures to allow the pulmonary artery to fall forward and away from the trachea. This procedure did not have a marked beneficial effect on the

Fig. Surgical procedure. The ligamentum arteriosum was divided to allow the pulmonary artery to displace forward. The anterior arch of the aorta was divided to relieve compression of the trachea.

respiratory exchange and the anterior segment of the ring was then divided between the two branches which were described.

As soon as the anterior aortic arch had been divided the respirations quieted down, most of the crowing disappeared and the respiratory shift in the mediastinum diminished to a normal degree. The chest wall was closed in an appropriate manner, the left lung being completely expanded before final repair of the wound and the patient was placed in a steam room and given sulfadiazine and penicillin parenterally.

After 1 week the patient was alert and playful and had no distress of any kind. When the ear was held close to the chest a faint inspiratory sound could be heard during and immediately following deglutition of food these inspiratory sounds became slightly louder, apparently because the esophagus was still displaced forward by the aortic arch behind it and was causing some pressure on the posterior wall of the trachea.

Röntgenographic examinations 3 months later showed no change in the esophagus, and the trachea still presented some narrowing above its bifurcation but this was distinctly less marked. Although its left border had straightened out considerably there was some indentation along its right side, perhaps due to some residual pressure from the left common carotid artery which was now passing across the trachea from in front, or due to incomplete develop-

ment of the tracheal ring following the longstanding external pressure.

Vascular rings of this nature do not always give rise to important clinical symptoms, but when the compression of the trachea is great enough to give rise to respiratory distress, surgical division of some portion of the ring should offer an excellent chance for relief of the symptoms.

JOHN IV. BARNES, M.D.

ESOPHAOGUS AND MEDIASTINUM

Lam, C. R.: Surgical Treatment of Congenital Atresia of the Esophagus. *J. Pediatr. S. Soc.* 1945 27:456

Until Leven in 1939 reported that a child had survived the serious preliminary operations of a multiple stage procedure for congenital stenosis of the esophagus, and that if an antethoracic skin tube could be constructed the case could be called successful the outlook for the child born with an obstructive defect in the esophagus was hopeful.

The indirect method, however, had many disadvantages and it soon gave way to the operation of direct anastomosis.

Esophageal atresias may be classified as follows: type 1 in which there is complete absence of the esophagus (rare); type 2 in which there is an upper and a lower segment ending in blind pouches (also rare); type 3 in which one or both of the segments communicate with the trachea or bronchus. Type 1 is subdivided into type 3a, in which the fistula is between the upper segment and the trachea, type 3b, in which the fistula is between the lower segment and the trachea, and type 3c, in which both segments communicate. Type 3b is encountered more frequently than all other types combined and accounts for from 80 to 90 per cent of all congenital atresias of the esophagus.

If a newborn infant has a tendency to choke on its own mucus or is unable to take feedings, reliable roentgen studies should be carried out and if a congenital lesion is present, its type can be determined with considerable certainty.

For a successful operation, three objectives are in order: (1) provision must be made for feeding the infant; (2) regurgitation from the stomach through the lower segment into the trachea and bronchial tree must be prevented; (3) the blind pouch of the upper segment must be opened to allow the escape of swallowed saliva. These requirements would be met by gastrostomy, ligation of the lower esophageal segment and marsupialization of the upper pouch. With these three procedures completed, the situation would be compatible with life, but permanent gastrostomy feedings would be necessary unless an antethoracic esophagus could be constructed. On the other hand, the operation of direct anastomosis meets at once all the essentials for the establishment of normal functional and anatomic conditions.

Most or all of the operation is performed under local anesthesia. A transfusion of approximately 15

SURGERY OF THE THORAX

c.c. of blood is given through a cannula inserted in an ankle vein. Access to the posterior mediastinum is gained by exposure of the vertebral ends of the second through the sixth ribs, subperiosteal resection of short lengths of these ribs, section of the third, fourth and fifth intercostal bundles, and careful reflection of the parietal pleura from the vertebral column. It is necessary to ligate the azygos vein on the right or the upper two or three intercostal arteries on the left, to open up the space behind the trachea where search will be made for the distal segment. The upper segment is identified by the palpation of a catheter which has been introduced through the mouth. The lower segment is then located and ligated as close to the ligature as possible. It is cut transversely distal to the ligature and a corresponding opening is made in the blind upper segment. End-to-end anastomosis is performed over a catheter and with the use of fine silk suture or eye needles. If no distal segment can be found or if after ligation the segment is too short to be connected with the upper one, resort to an indirect method is made.

Immediate postoperative care consists in an oxygen tent incubator, extreme vigilance in the aspiration of secretions from the pharynx and nothing by mouth for 5 days. Parenteral fluids being administered by hypodermoclysis. On the fifth day, if inspection of the dressing shows no leakage of mucus from the wound, cautious feeding by mouth is begun. One-half ounce of 5 per cent dextrose solution is offered every two hours. If there is no regurgitation or evidence that the anastomosis is not intact this amount is gradually increased to 1 ounce. On the seventh postoperative day 1 ounce of formula is given every 3 hours. If this is tolerated all restrictions on the feeding of formula are removed after the tenth day. Vomiting should be avoided for it would undoubtedly put strain on the anastomosis.

STEPHEN A. ZIEGLER, M.D.

Scott W. J. M.: Idiopathic Dilatation of the Esophagus. *Ann Surg* 945:131-138.

Today it is recognized that dilatation of the esophagus without obvious pathological cause is a common condition. In fact it is approximately one third as frequent as carcinoma of the esophagus, being second only to the latter in the statistics of the larger clinics (MacMillan). It appeared earlier in the literature under the purely descriptive term, ectasia or idiopathic dilatation of the esophagus. But today the author's etiological conception is usually introduced into the name, and the condition is most commonly designated as achalasia of the cardia or cardiospasm although there are still widely conflicting opinions about the cause of the dilatation.

Fortunately for the patients who suffer from this serious and usually progressive difficulty in the passage of food from the dilated esophagus into the stomach, treatment does not need to wait for a final determination of the cause by dilatation of the

cardia, either on one or repeated occasions, the symptoms in the majority of cases are adequately controlled. However some of these patients do not respond satisfactorily to this and the other conservative measures of treatment. Although the percentage of this refractory group is small, the failure to respond to conservative measures offers a serious problem for two reasons: first, because of the complete failure of the usual therapeutic measures to alleviate the condition and, second, because of the progressive seriousness of the symptoms. These cases constitute a small but important group and their relief has become a challenge to the general surgeon as well as to the esophagoscopist.

Dilatation of the esophagus without any clinically discoverable obstruction is not a disease entity but a syndrome. At least four clinical types can be recognized each with a different etiology, namely: (1) achalasia of the esophagus, (2) true cardiospasm, (3) partial constriction near the cardia, and (4) dolichoesophagus.

Achalasia is probably the most common type. It usually responds well to dilatation. In true cardiospasm the reflex originating focus should be discovered and removed. Those cases caused by a covered and removed partial constricting band near the cardia are few in number but are probably resistant to conservative treatment. Dolichoesophagus, an S-shaped lengthening with pooling of esophageal contents at different levels, should probably be operated upon immediately on recognition. This type is very difficult to control when the dilatation becomes gigantic and is complicated by infection of the esophageal wall.

Subdiaphragmatic esophagostomy of the Finney pyloroplasty type appears to be the operation of choice in the cases of idiopathic dilatation of the esophagus that are resistant to the usual conservative measures. The symptomatic results of this operation are usually excellent whether or not the dilatation of the esophagus is entirely corrected. The danger of the operation is not excessive when proper precautions are taken. After this operation has been employed more extensively the number of cases in which it is indicated will probably be considered as having increased but it should never replace conservative dilatation in the majority of cases.

JOHN E. KIRKLAND, M.D.

Olsen A. M., O'Leary P. A. and Kirklin B. R.: Esophageal Lesions Associated with Acrodermatitis and Scleroderma. *Arch. Int. M.* 1945, 76:189.

Approximately 10 per cent of the patients suffering from acrodermatitis or scleroderma made complaints referable to the esophagus. The most common complaint was dysphagia. Frequently there was also subcutaneous burning after meals, especially when the patient was lying down. Positive roentgenographic or endoscopic findings were demonstrated in 18 cases. Dilatation of the esophagus similar to that seen in cardiospasm was

observed in 7 cases and hiatal hernia with intra thoracic stomach was demonstrated in 9 cases. In 2 other cases sclerodermic changes were demonstrated in the esophageal wall.

Acrosclerosis should be distinguished from other forms of scleroderma. In acrosclerosis the phenomena of Raynaud's disease are present prior to the dermatological changes or coincident with them. Thirty three of the 36 patients who had esophageal symptoms presented the clinical syndrome of acrosclerosis. All of the 18 patients who had positive roentgenographic or endoscopic findings had acrosclerosis.

The basic alteration in acrosclerosis and scleroderma is sclerosis of the connective tissues of the body. Sclerodermic changes in the connective tissues of the esophagus are chiefly responsible for the esophageal disturbances. It should be emphasized that esophageal disturbances are extremely uncommon in Raynaud's disease per se. Reduced or absent muscular activity in the wall of the esophagus and shortening of the esophagus apparently result from sclerodermic involvement. Disturbances of the autonomic nervous system may play some part in the causation. Clinical diagnoses of cardiospasm and hiatal hernia of the short esophagus type are made most frequently in these cases. Stenosis of the lower part of the esophagus and the esophagogastric junction may occur with hiatal hernia as the result of chronic inflammation of the lower part of the esophagus. This inflammation is the result of incompetence of the cardiac sphincter with regurgitation of the gastric secretions.

The treatment of the esophageal lesions of acrosclerosis consists of the passage of sounds over a previously swallowed thread. Fairly satisfactory results have been obtained. The esophageal stenosis of 1 of these patients was treated satisfactorily over a 16 year period by repeated dilatations.

Clark, D. E. and Adams, W. E.: Trans thoracic Esophagogastronomy for Benign Strictures of the Lower Esophagus. *Ann. Surg.* 1945 2 943

Clark and Adams report in detail 5 cases of trans thoracic esophagogastronomy for benign stricture of the lower esophagus. None of the 5 patients was considered to have cardiospasm. In 1 case the stricture followed the ingestion of lye, in another it was associated with generalized scleroderma, and in 3 cases there was no etiological factor that could be ascertained. In all of the cases however the obstruction either started above the diaphragm, or the entire lesion was in the thorax, so that transabdominal cardioplasty was out of the question.

Four of the patients had repeated dilatations with only temporary relief and 3 of these required gastrostomies when dilatations became impossible. The fifth patient because a malignancy of the cardia was suspected was not subjected to dilatation.

Employing positive pressure ethylene-oxygen-ether anesthesia the authors opened the chest through the eighth rib bed in 4 cases, and through

the eighth interspace in 1 case. After proper retraction of the lung and excision of the phrenic nerve, the diaphragm was incised from the periphery toward the esophageal hiatus. The spleen was removed to facilitate mobilization of the stomach and the fundus was brought up into the thorax in the arch of the aorta. The anastomosis spot was selected just above or at the upper level of the stricture and side to side anastomosis was made. The diaphragm was closed about the stomach and sutured to its wall. The wound was closed tightly.

All of the patients made an uneventful recovery and are still alive and enjoying a normal existence.

It is concluded from these selected cases of benign stricture of the lower esophagus that trans thoracic esophagogastronomy offers the patient complete relief without the necessity of dilatation or the unpleasantness of the gastrostomy.

STANLEY A. ZIMMER, M.D.

MISCELLANEOUS

Donovan, E. J.: Congenital Diaphragmatic Hernia. *Ann. Surg.* 1945 122 566.

In reviewing the literature of the past 10 years in congenital diaphragmatic hernia, one is impressed by the number of single cases reported by various authors as well as by the series of cases reported by Harrington, Ladd and Gross, and Hartel, and Truesdel. Many of the infants were operated upon successfully at an early age. It is obvious from these reports that the diagnosis is made much earlier and that operative treatment has made great progress in recent years. In 1935 Hedblom reported that 75 per cent of the infants with congenital hernia die before they are 1 month old. In 1938, the author reported 10 cases from the Babies Hospital, New York, 6 of which had been operated upon. The purpose of this article is to review the surgically treated cases of the first series, add to their follow up, and report 11 additional cases operated upon since 1941.

The most common congenital defects in the diaphragm are, in order of their occurrence: (1) esophageal hiatus, (2) foramen of Bochdalek, (3) foramen of Morgagni, and (4) defects in the dome. Hernias through the vena caval or aortic openings in the diaphragm have never been reported.

The symptoms of diaphragmatic hernia may be either circulatory, respiratory, gastrointestinal, or a combination of all three. They are due to mechanical interference with the function of the herniated structures or to interference with respiratory or circulatory organs upon which the herniated structures encroach. In most of the cases of hernia through the foramen of Bochdalek, the usual finding is that the chest is full of intestines, both large and small, often accompanied by part of the stomach and quite frequently by the spleen and kidney.

Surgical repair of the hernia should be advised immediately for all cases in which either the small or large intestine is in the chest because of the danger of intestinal obstruction. The author prefers the

SURGERY OF THE THORAX

abdominal approach through a subcostal incision with exposure of the phrenic nerve in the neck 48 hours before repair. Many surgeons prefer the thoracic approach. As a rule there are no adhesions in the chest and the structures are easily reduced if the operator places a retractor in the diaphragmatic defect and equalizes the pressure in the chest and abdomen before he tries to reduce the structures.

In 3 cases of this series there was a large opening with no attachment of the diaphragm to the posterior chest—these were probably cases of deficiency of or chest—these were probably cases of deficiency of the diaphragm. In these cases a row of silk sutures was used with two needles on each. They were passed through the diaphragm to the outside of the chest wall, one on either side of the adjacent rib and tied over a piece of gauze. Because of the deficiency of reparative material in these cases, the row of sutures attached the diaphragm at a higher level in the chest than normal in closing the defect. A second row of continuous or interrupted silk sutures were then used to attach the edge of the diaphragm to the pleura and intercostal muscle. In any type of closure a catheter is placed in the chest and the air is removed before the last suture is tied.

Positive pressure or intratracheal anesthesia are very desirable. All patients should be kept in an oxygen tent for several days after operation. Pleural effusion may occur and aspiration should be done as necessary. JOHN E. KIRKPATRICK, M.D.

Greer, A.: Two Cases of Mediastinitis Caused by Perforation of the Esophagus and Treatment with Penicillin. Recovery. (Dos casos de mediastinitis por perforación esofágica. Tratados con penicilina. Curación.) *Rev med Chile* 1945 73 979 *Rev otorinolaringol* 1945 5 115

The customary treatment of mediastinitis caused by perforation of the esophagus consists of mediastinotomy especially if the perforation is located in the upper esophagus, while a partial resection may be indicated in grave cases.

A perforation of the esophagus may be due to a voluminous foreign body or one with irregular surfaces or sharp points. In other cases a cancer or ulcer of the esophagus may lead to a perforation or the latter may be due to a traumatism in the course of esophagoscopy. A violent spasm provoked by an attempt to extract a large foreign body through an esophagoscope may be followed by a perforation.

If a perforation occurs in the cervical portion of the esophagus pain develops at the base of the neck and a subcutaneous emphysema appears. If the perforation involves the thoracic portion of the esophagus the pain is confined chiefly to the region between the scapulae, and the respiratory movements become shallow because deep respiration causes pain. If the perforation occurs in the distal portion of the esophagus the pain is confined mostly to the epigastric region. Anxiety, pallor of the skin and visible mucous membranes, frequent pulse, and the presence of anaerobic bacteria in the sputum and fever are other important signs.

The author treated an 18 year old girl who developed dysphagia following the ingestion of 10 c.c. of nitric acid. Two months later roentgenograms showed a cicatricial stenosis of the esophagus of caustic origin. The entire esophagus was rigid and stenosed. On esophagoscopy examination a stenosis was encountered at the upper aperture, and sounds, from size 12 to 18 were introduced through Jack's tube. The patient's condition improved but she returned 9 months later with intensive dysphagia. Sounds from size 12 to 14 would pass only the upper portion of the esophagus and roentgenographic studies confirmed the diagnosis of a high stricture. Dilatations of the esophagus were continued for 11 days. Two weeks later the patient returned with a more intensive dysphagia and edema and pains in the left side of her chest. The pains were radiating toward the left upper extremity and the left side of the spine. Gastrostomy was planned in order to facilitate alimentation. X-ray studies revealed a homogeneous, sharply circumscribed shadow in the upper mediastinum especially on the left side. The esophagus in that region had irregular outlines and a retention of barium was noticed 24 hours after its ingestion. The roentgenological diagnosis was mediastinal abscess of esophageal origin with a suspicion of pulmonary abscess on the left side. Twenty thousand units of penicillin were given every 3 hours in addition to a blood transfusion. The temperature returned to a normal level after 48 hours and the pain disappeared completely after the administration of 1,000,000 units of penicillin. Five days later x-ray studies showed a complete disappearance of the mediastinal lesion. It was believed that this lesion might also have been of tuberculous origin.

The second patient, 33 years of age had been complaining of epigastric pains and complete dysphagia for 4 years. The attacks used to come in the form of crises during which the patient was not able to swallow even his saliva. Gradually the attacks returned at shorter intervals so that at the time of admission hardly a day was passed without attacks. Roentgenographic studies revealed a contraction of the esophagus at the junction with the cardia. An esophagoscope 7 by 45 could not pass the stenosis. A dysfunction of the diaphragmatic hiatus with a resulting spastic condition of the esophagus was diagnosed and a mercury sound was passed. The procedure was repeated for 4 days. When the esophagoscopy examination was repeated a constricture was encountered at the cricopharyngeal level. The esophagoscope was withdrawn but in spite of careful technique the patient developed pain in the neck, especially on the left side. Frequent pulse, and a rise in temperature. Roentgenographic examination disclosed a sharply circumscribed homogeneous shadow in the upper mediastinum. The clinical and roentgenological diagnoses were mediastinitis due to a perforation of the esophagus. Thirty thousand units of penicillin were given intramuscularly every 3 hours, in addition to a hypodermic

moclysis of glucose in saline solution. The follow ing day an edema developed in the left lower cervical region and the frequency of respirations rose to 30 per minute. The pain was radiating to the left side of the chest and the left supraclavicular region. Only after 72 hours the fever, pains, dyspnea and other symptoms began to subside and it disappeared completely 10 days from the time the treatment had been instituted. The total amount of penicillin given was 1,020,000 units. A gastrostomy was performed to facilitate the administration of food and retrograde dilatation.

The author stresses the point that in spite of a large experience of the esophagoscopist and extreme care, fissures of the esophageal wall may follow dilatation of the esophagus. A necrosis of the mucosa gradually leads to the formation of a fistula with resulting mediastinitis. Blood transfusions and the administration of other fluids intravenously should supplement the administration of penicillin in such cases.

JOSEPH K. ARAT, M.D.

Forsee, J. H.: The Use and Control of Thoracic Surgical Teams of an Auxiliary Surgical Group. *J. Thorac. Surg.* 1945 14 495.

An auxiliary surgical group composed of a group headquarters, general surgical, orthopedic, neurosurgical, maxillofacial, thoracic surgical, shock gas, and dental prosthetic teams has been employed in the American Army for the first time during World War II.

This organization under one central control group has produced a maximum level of competence and economy in the deployments of specialized surgical talent. Remarkable advances have been made in thoracic surgery since World War I and thoracic surgical teams have been used for the first time in this war. The author's study is based on 15 months of experience caring for 3000 patients with thoracic injuries.

Thoracic surgical teams are composed of a thoracic surgeon, an assistant surgeon, an anesthetist, a surgical operating room nurse, and 2 enlisted surgical technicians. The chief surgeon should be a competent operator preferably with a sound basic training in general surgery, a good teacher and should have a thorough knowledge of surgical physiology of the thorax. The assistant surgeon should have a minimum of 2 years of surgical training with some experience in the medical aspects of thoracic diseases. The anesthetist should be expert in endotracheal and positive pressure anesthesia. In bronchoscopic aspiration of secretions, the management of shock, and in the recognition and treatment of disturbed cardiorespiratory physiology. The nurse should be an able instructor in operating room technique, able to teach the principles of asepsis to soldiers without previous experience, and have a knowledge of the technical features of the specialty. All team members should be sincere, have physical stamina, and the ability to adapt themselves to varied and changing situations.

The teams work in many different hospitals to supplement the regular staffs when the requirements for surgery exceed the capacity of the regular staff.

The equipment is minimal and consists of the army basic instrument set, and a supplemental thoracic set including a bronchoscope and accessories. An electric suction apparatus and portable anesthesia equipment complete the list.

The thoracic surgical teams are employed in forward and base section areas. The most severely wounded those who cannot be transported further to the rear without surgery are cared for in a phase of a small field hospital. Ordinarily a field hospital can care for 380 patients, but when used as a first priority mobile surgical hospital, the cases must be reduced to about 35. The small staff is supplemented when necessary by the qualified personnel of the surgical teams of an auxiliary surgical group.

It is here that surgical care can be first initiated. These hospitals are located in the rear of a division area and in close conjunction with a division clearing station. The platoons of a field hospital are capable of moving on short notice and they "leap frog" one another. The platoon, or part of it, is held behind and becomes a holding unit. When all the patients have been evacuated, in from 1 to 10 min the unit is available to "leap frog" another platoon and become the forward hospital.

An active platoon requires 4 general surgical, 1 thoracic, and 1 shock team. The thoracic surgical team not only operates but also advises in the management of thoracic wounds and teaches bronchoscopy to anesthetists and surgeons. The thoracic surgeon is interested in intercostal nerve block, pre and postoperative thoracentesis, endotracheal and positive pressure anesthesia, pulmonary resection after surgery, catheter aspiration of tracheobronchial secretions, the management of hemothorax, foreign bodies, and traumatic hemothorax has been a stimulus to all surgeons treating severe thoracic wounds.

Certain types of cases which were considered first priority surgical problems, in the light of certain therapeutic measures previously enumerated together with judicious shock management, are now frequently transportable, and immediate surgery is no longer considered necessary. One thoracic surgical team, however, during a period of 7 weeks, operated on 92 intrathoracic conditions, of which 16 were combined thoracoabdominal wounds, 16 were thoracotomies and 56 were penetrating or perforating injuries. At the same time this group operated on 44 patients with abdominal wounds.

First priority surgical cases represent only 3 per cent of the total cases arriving at the division clearing station. The majority are evacuated to the evacuation hospital a few miles to the rear. The mortality rate in a well run first priority hospital is about 25 per cent, and anything less usually indicates an improper selection of cases.

The overall mortality rate in 346 intra-abdominal wounds (20 per cent of which were combined thoracic

thoracoabdominal wounds) treated by surgeons of this group was 30.6 per cent. Pulmonary complications caused 27 per cent of the deaths, while peritonitis was responsible for only 11.4 per cent. Another series of 226 intrathoracic wounds with 43 per cent thoracoabdominal injuries showed an overall mortality of 28 per cent.

These figures indicate that most patients were wounded with high explosive shells, and that the highest percentage had multiple major wounds. Thoracic surgical teams working at this level must be competent to do major abdominal surgery.

The surgical teams of an auxiliary surgical group have done much to develop the phase of forward surgery. They have exerted a remarkably favorable influence on the morale of combat troops and have eliminated the temptation for clearing and collecting companies to indulge in heroic surgical procedures which they were never designed or equipped to carry out.

The evacuation hospitals, located from 3 to 15 miles in the rear of a first priority surgical hospital, treat 90 per cent of the casualties from the divisional clearing stations. The percentage of abdominal and combined thoracoabdominal injuries treated here is low, but a majority of the penetrating injuries of the thorax are treated here. An appreciable segregation of cases into the surgical specialties is practical. In such 400 or 750 bed installations, thoracic surgical teams have been useful to supplement the regular thoracic surgical section or furnish qualified personnel if no qualified thoracic surgeon is on the regular staff. It is highly desirable to have a thoracic surgical team functioning in an evacuation hospital and devoting their attention to the treatment of patients with major thoracic injuries.

In quiet periods at the front when there is no need for beds for imminent battle casualties, certain surgical procedures such as the removal of intra-pulmonary foreign bodies and pulmonary decortication for organizing hemothorax are undertaken.

In fixed installations, station or general hospitals in the base section area, the thoracic surgeons have a real opportunity. Every effort is made to return the patients to duty within 90 days. This policy has led to several noteworthy contributions: the removal of intrapulmonary foreign bodies within 10 days to 3 weeks after injury; the radical management of massive organizing hemothorax by thoracotomy; evacuation of the clot and decortication of the lung. The same procedure applied to established post-traumatic empyema with penicillin therapy as an adjunct has led to immediate healing with a fully expanded lung. This has been one of the significant advances in the surgery of World War II. To the thoracic surgical teams of an auxiliary surgical group goes much of the credit for these advances.

The use of thoracic surgical teams in fixed installations often has permitted the completion of the reparative phase of surgery by the same surgeons that have dealt with the initial phases of wound management in the forward hospitals.

The organization of a large number of highly trained surgeons into surgical teams under one central control was new and untried several years ago. Few hospitals considered the need for the assistance furnished by such teams. However, today the usefulness of such an organization is fully recognized and appreciated by all who have first hand experience in the problems confronting the medical science of an active theatre of operations.

RONALD R. BRADLOW, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Brandon, W J M: Inguinal Hernia; The New Muscular Internal Ring *Lancet* Lond. 945 249 8 2

The author points out that the only common factor in the various types of hernia repair is the retention of the original muscular internal ring. Closure of this ring when the cord and testicle are removed has proved uniformly successful. The conclusion is drawn that the internal ring is the potential source

Fig. 1. A, Incision of internal oblique and transversalis muscles. B, conjoined tendon. C, spermatic cord.

Fig. 2. A, Incised muscles reconstituted to form new muscular internal ring. B, entire inguinal canal closed by suture of conjoined tendon to Poupart ligament.

Fig. 3. A, Portions of internal oblique and transversalis muscles sutured medial to cord. B, sutured conjoined tendon. D, transversalis fascia. E, lateral portion of internal oblique and transversalis muscles.

Fig. 4. A, Internal oblique and transversalis muscles incised. F, muscles separated in the line of their fibers. (Spermatic cord omitted.)

Fig. 5. New muscular internal ring full constructed.

Fig. 6. A, B (sutured conjoined tendon) Anterior blade of shutter giving full protection to true internal ring. C, spermatic cord emerging from new muscular internal ring after taking an S-shaped bend. D, transversalis fascia forming posterior blade of shutter and protecting new muscular internal ring. E, internal oblique and transversalis muscles. G, dotted lines showing path taken by spermatic cord in all well-known posterior repair operations.

of weakness and that all recurrent hernias may be shown to involve the internal ring.

A modification of the Bassini repair is described, in which the essential feature is the construction of a new muscular ring. The internal oblique and transversalis abdominal muscles are incised so as to form a "V" at the old internal ring. This muscle is then sutured about the cord to form a new ring, as shown in Figs. 1, 2 and 3. A slightly different technique in which the fibers of the muscles are split at the apex of the "V" to further move the internal ring from its original position, is shown in Figs. 4, 5 and 6. In this way the obliquity of the emergence of the spermatic cord from the abdomen is changed and made more angular. There is then a two bladed "shutter" over the internal ring—one the transversalis fascia, another formed by the new muscular ring, and both permanently closed and not in opposition to one another.

The author concludes that for the moment this new suggestion in the repair of inguinal hernia is a thesis and that proof of its efficacy must await the test of time.

THOMAS C. DOUGLAS, M.D.

GASTROINTESTINAL TRACT

Candino, A. The Arterial Circulation of the Stomach. Gastric Hemorrhage (*Circulación arterial del estómago. Hemorragia gástrica*) *Rev Gastroenterol* 945 10 91

The author removed the stomach and the adjoining part of the duodenum from cadavers, preserving all the arteries. Specimens were obtained from fresh cadavers to avoid maceration of the tissues. The main arteries were injected with a radiopaque substance and roentgenograms were taken. In this manner the author studied the distribution of the blood vessels in normal stomachs and in those with peptic ulcers.

He came to the conclusion that there is a perfect equilibrium between the arterial pressures of the main arteries. Various factors collaborate in the regulation of the pressure, velocity, and quantity of the blood passing each branch. One could expect that a peristaltic contraction might produce an anemic zone because of the compression of the blood vessels, but in reality this is not the case. The direction of the main arteries is identical with that of the peristaltic waves, which facilitates the blood flow. Numerous anastomoses also contribute to the maintenance of a continuous blood current.

The diagnosis of the origin and mechanism of a grave gastroduodenal hemorrhage is of paramount importance in the selection of proper treatment, namely the choice between a pure expectant treatment, active medical therapy and surgical intervention. The gravity of anemia must be determined by a study of the blood pressure, pulse, blood count, and

the amount of hemoglobin. The determinations of pulse and arterial pressure are of limited value because shock may produce a similar picture. Therefore the blood count and determination of the amount of hemoglobin are of greater value. A grave hemorrhage in the stage of evolution produces a pulse of gradually increasing frequency and an arterial pressure which gradually falls. On the other hand shock is followed by a fall of the blood pressure which remains stationary for a time, but gradually returns to normal levels in favorable cases.

A grave hemorrhage causes a progressive diminution of the number of red blood corpuscles. As a rule, an acute hemorrhage responsible for a fall of the number of erythrocytes to 3 000 000 within the first 3 hours gives a very grave prognosis. A red blood count of as little as 1 to 2 million is compatible with life, while in chronic anemias the organism may survive a count even lower than 1 000 000 erythrocytes.

An amount of hemoglobin lower than 30 percent is not compatible with life and therefore a fall of hemoglobin in between 40 and 50 per cent requires a blood transfusion.

A pulse frequency between 130 and 150 gives a serious prognosis and a systolic pressure between 80 and 90 is also alarming.

While laboratory examinations furnish information as to the gravity of symptoms, clinical examination should attempt to establish the cause of hemorrhages. It must be remembered that various conditions may be responsible for a gastroduodenal hemorrhage, e.g. ulcers, hemophilia, gastric varicosities, venous hypertension caused by a cirrhosis of the liver, blood dyscrasias caused by cholelithiasis, primary or secondary gastric hemorrhage produced by Banti's disease, syphilis of the stomach, cancer and congestion within the stomach wall caused by retention due to pyloric stenosis.

Hemorrhages from capillaries or precapillaries are benign, as a rule, while those from larger blood vessels require a surgical hemostasis.

If conservative treatment is decided upon, an icebag should be placed in the dorsolumbar region, and not over the epigastrium because the vasoconstricting reflex of neurogenic origin can be stimulated easier in this manner. Liquids should be given hypodermically in preference to their intravenous administration in order to avoid an overloading of the circulatory system. The amount given depends on the quantity of lost blood, the condition of the pulse, and the blood pressure. The amount of blood to be transfused also should be related to the amount of blood lost.

In chronic anemia a relatively small amount of transfused blood may raise the blood pressure, but this is not the case in patients with an acute hemorrhage who tolerate large amounts of blood without a rise in their blood pressure. A few days may elapse before the blood pressure returns to normal limits after a transfusion of relatively large amounts of blood. A patient with 3 000 000 erythrocytes a

hemoglobin of 60 per cent, and a systolic pressure of 100 requires larger amounts than 400 c.c. of blood.

Vitamin K should be administered intravenously in sufficient amounts. The oral administration of bismuth is to be condemned because the drug has no local hemostatic effect and may provoke vomiting.

No food whatsoever should be given during the acute hemorrhage, but after the bleeding has stopped spontaneously or under the influence of treatment, liquids and later on the white of an egg, gelatin and chopped meat may be offered.

An internist should treat the patient with acute gastric hemorrhage until the etiology of the condition has been established. The cause of hemorrhage is the determining factor in the choice of definite treatment.

The roentgenological studies of the gastric arteries convinced the author that an efficient hemostasis requires extirpation of the source of the hemorrhage.

JOSSEPH K. VAKAT, M.D.

Dragstedt, L. R.: Vagotomy for Gastroduodenal Ulcer. *Ann. Surg.* 1945 122 973.

In this communication the author reports the present status of section of both vagus nerves in the treatment of peptic ulcer. The operation was undertaken because of the conjecture arrived at by experimental work on the lower animals that pure gastric juice as secreted by the fundus of the stomach has the capacity to destroy and digest various living tissues including the wall of the jejunum, duodenum and even the stomach itself. The chief secretory abnormality in ulcer patients lies not in the production of a juice with higher than normal acidity, nor even in the production of more normal juice in response to the usual stimuli, although there is some evidence that this occurs, but rather in the secretion of abnormally large amounts of gastric juice in the intervals between meals, particularly at night when the stomach is empty and there is no obvious stimulant.

Through animal experimentation it was found that section of the vagus nerves to the stomach reduced the secretion of gastric juice in dogs to one half or even one fourth of the normal level. The data obtained so far suggest that the hypersecretion of gastric juice in ulcer patients is neurogenic in origin and that, consequently, a comparatively greater reduction should follow vagus section in man than in lower animals.

In all the author and his associates have operated upon 39 patients with peptic ulcer by sectioning the vagus nerves. The transthoracic approach by resection of the seventh or eighth rib is preferred to the abdominal approach although the latter has been used in 7 cases.

Postoperatively, the author employed the insulin test to determine if all the vagus secretory fibers to the stomach were interrupted. The rationale of the test lies in the fact that hypoglycemia induced by an adequate dose of insulin stimulates the vagus secretory fibers to the stomach, probably by an effect on

the central nervous system. No effect whatever occurs if the vagus section has been complete.

Of the 39 patients subjected to the operation at the time of this report, 1 died. This patient developed postoperative bronchopneumonia. Thirty of the patients in this series had duodenal ulcers; 3 had gastric ulcers and 7 had gastrojejunal ulcers. Eight of those with duodenal ulcer were subjected to gastroenterostomy in addition to the vagus section because of high grade pyloric stenosis. In most of the cases of this type the vagus section was done by the abdominal approach at the same time as the gastroenterostomy. Only 1 of the patients with duodenal ulcer failed to obtain striking and persistent relief from his symptoms and in this case there were many features suggesting a neurosis. The first group of patients have been followed up for 2½ years and, so far, have remained well on unrestricted diets and without medication. For the remainder of the patients a longer period of observation is required before conclusions can be drawn, especially in the cases of gastrojejunal ulcer.

The operation has no effect on the secretory response of the stomach to histamine or caffeine but abolishes the stimulating effect of insulin hypoglycemia and a sham meal. Vagotomy reduced gastric secretion in the empty stomach at night from 50 to 60 per cent. It also resulted in the reduction of hypertonicity but the tone and motility of the stomach were not abolished. An interesting observation was the fact that patients who complained of constipation before the operation were relieved of this disturbance. Further study of this effect is necessary.

HAROLD LAUFMAN, M.D.

Riera, M., and Diaz, F. Low or Infrabulbar Duodenal Stenosis (*Estenosis duodenales bajas infrabulbares*). *Rev. med. Chile*, 945 73 855

In the majority of cases of duodenal stenosis the narrowing is located in the bulb and caused by a peptic ulcer. Roentgenograms show a pyloric stenosis with a secondary dilatation of the stomach. Stenosis in the lower segments of the duodenum is rare and may be due to various factors. As a rule, roentgenological studies allow a correct diagnosis and often throw light on the nature of the lesion.

An infrabulbar duodenal stenosis may be congenital or acquired and of intrinsic or extrinsic origin. A congenital stenosis is usually caused by a malformation. Complete duodenal atresia is incompatible with life. A ring of atrophic pancreatic tissue may cause a compression of the duodenum. In such cases a concentric stenosis of the second portion of the duodenum with smooth borders is seen in the roentgenograms. A diverticulum may produce a duodenal stenosis, especially when it is filled with food. In this respect the condition may be compared with stenosis of the esophagus caused by a distended Zenker's diverticulum.

A spastic condition must be taken into consideration in an acquired duodenal stenosis. Such spasm may be caused by a stone impacted in the common

duct. Roentgenograms are essential for the diagnosis in such cases. Tumors of the duodenal wall or an extrabulbar peptic ulcer may produce a stenosis of the duodenum. A cancer of the duodenum responsible for a stenosis has been reported. In the majority of cases an infrabulbar stenosis is due to an extrinsic lesion. The second portion of the duodenum may be compressed by the middle colic artery if ptosis of the right portion of the colon changes the normal position of the blood vessel. The root of the mesentery may compress the duodenum in patients with an intestinal ptosis or a short mesentery. In such cases the duodenum is compressed between the spinal column and the mesentery. There is also an acute type of arteriohepatic stenosis the mechanism of which is still under discussion.

An extrinsic infrabulbar stenosis may be caused by a tumor in one of the adjoining organs, either by compression or infiltration of the duodenal wall. Tumors of the gall bladder, pancreas, liver or the left kidney may cause a compression of the duodenum. Acute hemorrhagic pancreatitis may be followed by an enormous increase in the volume of the organ, with compression of the duodenum.

Mesenteric lymph glands enlarged on account of Hodgkin's disease, leukemia, or lymphosarcoma may produce infrabulbar compression of the duodenum. An aneurysm of the aorta may also be responsible for such a compression. Periduodenal adhesions, pericholecystitis, plastic postoperative peritonitis, or congenital bands may cause a compression of the infrabulbar portion of the duodenum.

Roentgenographic studies reveal a dilatation of the duodenum above the stenosis and an abnormally long retention of the ingested barium. A vigorous palpation of the involved region may provoke antiperistaltic waves and in the presence of pyloric insufficiency a reflux into the stomach may be observed. An obliteration of the mucosal folds is typical for the distention above the stenosis. If the stenosis is not complete, irregular contours of the duodenum may be noticed in the roentgenograms. Introduction of an opaque substance through a duodenal sound may prove useful. Peristaltic movements of the normal duodenum may be confusing and therefore repeated examinations are desirable. A supernumerary duodenal loop in the second portion of the duodenum may also create confusing images.

The authors report 11 cases of infrabulbar duodenal stenosis, 5 in men and 6 in women. In 9 it was possible to establish a definite etiology while in 2 the cause remained doubtful. The ages of the male patients ranged from 22 to 42 years and of the female from 40 to 78 years. JOSEPH K. NARAT, M.D.

Hoot, A., Five Cases of Cholecystoduodenostomy (*A propos de Cinq cas de cholecystoduodenostomie*). *Union med. Canada*, 946, 75 24.

As a rule, cholecystogastrostomy is preferred to cholecystoduodenostomy although it is a less physiological method. If technical difficulties are encountered,

tered occasionally a cholecystojejunostomy is performed although it is the least satisfactory method.

In the course of 10 years the author performed 5 cholecystoduodenostomies and only 2 cholecystogastrostomies. Usually these operations are done on account of bile fistulas with great loss of bile or on account of retention icterus. The last mentioned indication was present in 4 patients in the author's material. All of them had a cancer with numerous metastases in close vicinity to the primary tumor and at distant places. In 2 patients jaundice was due to carcinoma of Vater's papilla in 1 patient it was due to a cancer of the pancreas and in a fourth it was due to a malignant tumor of the common duct.

In 4 cases the anastomosis was employed as a palliative measure to limit bile drainage to suppress jaundice and to create in the patients the impression that they were cured. The patients survived the operation 14 months, 3 months, and 1½ months, respectively while the fourth patient succumbed to a bronchopneumonia on the eighth postoperative day.

As a rule patients undergoing cholecystoduodenostomy are undernourished and icteric and suffer from pruritus which interferes with their sleep. Small and frequent meals of easily digestible food are prescribed. The preparation of the patient for the operation should not exceed from 8 to 20 days and therefore oral feedings are supplemented by the subcutaneous administration of 5 per cent glucose solution 500 c.c. in 24 hours, with the addition of from 10 to 30 units of insulin. The fact should be remembered that such individuals easily develop a hypoglycemic crisis.

In view of the fact that the majority of patients requiring this type of an operation are cachectic and have hypotension a daily injection of from 4 to 6 c.c. of adrenal cortex extract divided in two doses, is given. The author avoids ephedrine on account of the resulting insomnia. However in the course of the operation an injection of 2 c.c. of ephedrine with 5 c.c. of adrenal cortex extract is given. From 6 to 10 c.c. of this extract are administered daily for the first 3 days following the operation and lesser amounts are given thereafter until the patient is able to get out of bed.

A hypnotic is given to provide sleep. As a rule the hypnotic is combined with 10 drops of a mixture of equal amounts of tincture of belladonna and tincture of stramonium to intensify the action of the barbiturates.

To diminish the hemorrhagic tendency of icteric patients, from 10 to 20 c.c. of a 10 per cent calcium chloride solution are given intravenously every day for 4 days preceding the operation.

No food is given by mouth the first 48 hours following the operation and during that time 1000 c.c. of normal saline solution, from 30 to 40 c.c. of a 10 per cent saline solution, and from 1000 to 1500 c.c. of glucose solution with 20 to 40 units of insulin are given when necessary.

Except in 1 case, the author employed local anesthesia combined with a basal anesthetic. The

anesthetic given per rectum consisted of chloral (4 gm.) potassium bromide (4 gm.) 1 yolk of an egg and milk q.s. ad. 300 c.c. for local anesthesia. The author used from 60 to 80 c.c. of a 1 per cent solution of novocaine without the addition of adrenalin because the latter produces a temporary hemostasis followed toward the end of the intervention by a reflex vasodilatation and oozing. After the peritoneal cavity has been opened a mesocystoduodenocolic anastomosis is obtained with a 0.5 per cent novocaine solution.

After the bile has been aspirated from the gall bladder the organ is united with the second portion of the duodenum. Sometimes it is necessary to separate the gall bladder from the lower aspect of the liver. Catgut No. 00 is used for the anastomosis. The rent is about 2 cm. long. The incision in the duodenum is made in the vertical direction. The second row of sutures is made with linen or chromic catgut No. 00. Sometimes omentum is attached to the suture line. Two drains are inserted one into the subhepatic region and the other at the site of the anastomosis. The drains are left in place from 24 to 48 hours.

JOSEPH K. NARAT, M.D.

Spatalisano B.; Atypical Initial Reticuloendothelioma of the Jejunum Associated with Chronic Stenosing Jejunitis (Reticuloendothelioma atipico iniziale del digiuno associato a digitulite cronica stenoiante). *Gior. Ital. Chir.* 1945, 1, 35.

The author describes the combination of a chronic, nonspecific inflammatory process with a tumor formation of reticuloendotheliomatous character in a 45 year old woman who was admitted with complaints of pain in the epigastrium of 1 year's duration. She vomited on rare occasions. Diarrhea alternated with constipation. A considerable degree of malnutrition was present. Roentgenographic studies disclosed duodenopyloric stenosis.

An operation was performed under a combined basal and local anesthesia. A deformity of jejunum 7 cm. long was found 3 cm. from Treitz ligament. In the involved region the intestinal wall was thickened and indurated and the corresponding mesentery was infiltrated and contained numerous small lymph nodes. There was a sharp line of demarcation between the affected portion and the adjoining healthy tissue. The lesion was resected and an end-to-end anastomosis was performed. The patient recovered.

Reticuloendothelioma is characterized by (1) a mesenchymal aspect and the capacity of producing reticular fibrillae (2) phagocytic activity (3) syncytial structure, and (4) the tendency to develop chiefly in endothelial direction. The following varieties may be distinguished (1) tumors with a mesenchymal aspect, (2) tumors with a reticular aspect (3) tumors with a pulposplenic aspect (4) giant cell tumors, and (5) tumors with an endothelial aspect.

The inflammatory process in the author's case resembled regional ileitis. The author believes that

the tumor developed following the inflammatory process.

JOSEPH K. VARAT, M.D.

Tan, C. C., and Liu, Y.: Amebic Colitis with Special Reference to Perforation. A Study of 20 Autopsied Cases. *Chin M J* 1945 6 366.

During a period of 19 years the clinical diagnosis of amebic colitis was made in 349 patients in the hospital of the Peking Union Medical College. In 9 of 20 cases in which autopsy was performed, perforations were found. Eleven of 20 patients gave no history of dysentery of those with perforation all except 1 were admitted with symptoms and signs of acute amebic dysentery which had been present from 1 week to 4 months. Of the entire series of cases more than half showed varying degrees of diffuse ulceration usually in the sigmoid colon and the cecum. The cecum presented the most severe lesions and the largest number of perforations. The ileum was involved in 7 of 20 and the appendix in 5 of 15 cases examined. The cecum was perforated in 5 instances, the descending colon in 4, the sigmoid in 2 and the transverse colon in 1 instance. In 3 instances multiple perforations were found.

The authors point out that whereas the diagnosis of amebic colitis is usually simple that of perforation may be easily missed particularly if there is no history or previous diagnosis of amebic colitis. Abdominal distention, tenderness, and muscle spasm are the common early findings. Emetine is not effective in controlling perforation after the anatomical lesions reach an advanced stage. Once perforation of the intestine occurs, the chance of recovery is slight. One case in which the patient survived perforation of the cecum and the formation of a fecal fistula is reported.

WALTER H. NADLER, M.D.

Pfeiffer D. B., and Patterson F. M. S.: Congenital or Hereditary Polyps of the Colon. *I. A. Surg* 1945 2 606.

In every individual who is found to have rectal polyps a complete study of the intestinal tract is necessary. This includes proctoscopic examinations, barium enema studies (postevacuation films and double contrast studies), and, finally roentgenograms of the stomach and small intestine.

The family history of every individual with multiple polyps of the colon should be thoroughly investigated since this condition is often on an hereditary basis. Early diagnosis and treatment is very important for intestinal polyps tend to become malignant.

A satisfactory plan of treatment includes fulguration of the polyps in the anus, rectum and sigmoid followed later by ileorectosigmoidostomy and finally, by colectomy. The outlook for these patients is good if treatment is begun early.

Five cases of multiple polyps of the colon are reported 4 of which had a definitely hereditary aspect. The classification, etiology, pathology, symptoms, diagnosis and treatment of congenital

multiple polyps are discussed and special emphasis is placed on the tendency of the polyps to undergo malignant changes.

JOHN L. KIRKPATRICK, M.D.

Weinberger H. A.: Observations on Large Bowel Perforations. *Surgery* 1945 18 547.

In the Lenox Hill Hospital, New York, 19 cases of large bowel perforation were recorded among 1,400 autopsies during the last 10 years. Ten of the 19 cases were attributable to a perforation complicating diverticulitis, 7 were due to malignancy and 2 were due to perforation by mechanical agents within the lumen. Four recent cases in which autopsies revealed perforations of the large bowel are reported in detail.

Attention is called to the high morbidity and high mortality in diverticulitis complicated by perforation. The prognosis is also grave in large bowel malignancies that are complicated by perforation, which may cause the first serious symptoms in from 10 to 20 per cent of these cases.

Two unusual cases of perforation of the sigmoid due to an intraluminal insult are recorded, one was due to impaction of a fowl bone and the other was caused by rupture after a vigorously administered enema.

Treatment of perforation from any cause is essentially the same. The surgical measures stressed are early and generous drainage with a minimum of manipulation of the site of penetration and a proximal decompressive colostomy.

WALTER H. NADLER, M.D.

Meyer K. A., and Kozoll D. D.: Preparation for Surgery of Patients with Colon Lesions. *J. Coll. Surg.* 1945 9 249.

By virtue of a carefully planned preoperative operative and postoperative regimen, it has been possible to resect the colon if unobstructed, perform a primary "open" anastomosis, return the colon to the peritoneum without performing a proximal colostomy and close the wound without drainage with only one death among the first 26 patients with lesions of the left half of the colon who were treated in this manner. This was possible only because of the many physiological aids with which the authors were able to surround their surgical patients. The advantages of this procedure over previous ones in which a colostomy (either proximal to or at the site of resection) was required are: (1) a more radical resection is possible because no bowel has to be spared for use as a proximal or distal loop of the colostomy; (2) such complications of exteriorization operations as wound infection, herniation, prolapse, fecal fistula, obstruction, and stricture formation are obviated; (3) a temporary colostomy and the morbidity associated with its closure is avoided and (4) primary resection and anastomosis without proximal colostomy is a one stage operation with a shortened period of hospitalization and no return visits for subsequent operations.

The authors describe their preoperative management with special reference to diet parenteral amino acids plasma infusions blood transfusions succinylsulfathiazole vitamins enemas Levine tube suction complicating diseases and preanesthetic medication.

The importance of an adequate diet in patients with malignant lesions of the colon is best illustrated by the incidence of hypoproteinemia in this disease the authors have reported an incidence of 30 per cent, compared to the average incidence of 23 per cent in a large group of surgical lesions.

The value of amino acid digests for parenteral protein nutrition in human beings both to supplement that which can be given by mouth and to supplant oral feedings when the latter is unfeasible has been demonstrated. The availability of amino acids for intravenous use is an important adjunct to surgery and can often be lifesaving.

The use of plasma as a source of protein nutrition has long been recommended but subsequent experiences have indicated that it too has shortcomings.

If one remembers the constituents of blood one should not be surprised that whole citrated blood transfusions have proved the most important aid in the preparation of patients for operation. The authors believe there is a striking effect produced by whole blood with amino acids and they combine these two fluids in clinical practice on the theory that amino acids will be utilized for tissue protein metabolism whereas the whole blood will be more effective upon the circulating proteins.

Succinylsulfathiazole has been the single greatest boon to colon surgery and has given considerable confidence in the undertaking of primary colon resections by an open technique rather than to rely upon crushing clamps with which so-called aseptic anastomoses are carried out. With the advent of this plan of chemotherapy not a single instance of postoperative peritonitis has been seen in the authors' series of cases and only 1 patient developed a wound infection which required drainage.

The indications for vitamin therapy in the preparation of surgical patients are manifold. Most of these patients have a deficiency of one or more vitamins.

The first enema and cathartic are given prior to the start of succinylsulfathiazole therapy. The second enema is given during the 24 hour period preceding surgery; this is done to allow the drug to attain as high a concentration as possible.

Intragastric suction should be established before operation to prevent distention. Control of distention prevents tension on the suture line and is as effective as a proximal colostomy with regard to decompression. Also the intragastric tube will aspirate swallowed inhaled anesthetic gases if used and help prevent postoperative aspiration pneumonia. Still another value in the use of this tube lies in the fact that the patient can drink freely immediately after operation which minimizes the dangers of a postoperative parotitis.

Because most patients with colonic diseases are in the sixth and seventh decades, a proportionately higher incidence of diabetes hypertrophied prostatic disease hypertension and oral sepsis is present. Unless the patient is acutely obstructed all of these conditions demand correction before bowel resection is undertaken.

The authors describe their operative management with special reference to anesthesia open versus closed resections, sutures, wound repair blood transfusions Levine tube suction and vasoconstrictive drugs.

Whenever possible they have employed nupercaine spinal anesthesia which provided an adequate period of anesthesia without the use of inlying intraspinal needles.

Any attempt at following a so-called aseptic technique in anastomosis has been avoided deliberately, for it is believed that the use of clamps in closed resection is not without the danger of necrosis of the bowel edges and is cumbersome.

The authors employed the principle of fine interrupted sutures on atraumatic needles in the anastomosis and the wound as well.

Interrupted sutures are used in closing all layers of the wound.

Blood transfusions are given during the operation although the patient may have received 2000 c.c. or more of blood during the preoperative period. This is the most effective means of preventing shock and compensating the patient for blood loss sustained as the result of surgery.

Suction with the Levine tube is continued during the operative period to decompress the stomach which might otherwise obscure the operative field to prevent the swallowing of inhaled gases if given, and to prevent the aspiration of gastric content through emesis.

Vasoconstrictive drugs are given to prevent the drop in blood pressure frequently seen with spinal anesthesia the authors' particular preference is neosynephrin.

Granted that the patient is operated upon most skillfully after having been prepared as carefully as outlined a successful result will not be achieved unless he is given equally painstaking postoperative care. This care includes a wide variety of therapeutic adjuncts, many of which have been outlined in the preoperative regimen.

Attention must be paid to the physiological principles of fluid balance.

Blood transfusions were rarely necessary postoperatively in patients who have been given 2000 c.c. or more of blood before and during operation. However unlimited quantities of whole blood are administered to patients showing the need for it.

The rationale for the authors' use of parenteral amino acids has been discussed but the need for them is frequently more acute because of starvation which may follow colon surgery.

The rationale for gastric suction has been outlined. Suction should commence before the patient is sent

to the operating room continued during the operation and resumed immediately after his return to bed

Hyperventilation is employed routinely with mixtures of carbon dioxide and oxygen, and is administered every 1 or 2 hours until the patient breathes deeply or coughs. By this means greater oxygenation of the pulmonary alveoli occurs, mucus is dislodged and pulmonary complications are avoided. Oxygen is used routinely either with a nasal catheter or nasal mask in patients whose condition is precarious or who have a cardiac complication.

Vitamins are administered with the intravenous fluids in the dosages given during the preoperative period they are given orally when the patient resumes a diet, but are usually not necessary when he is ready to leave the hospital.

While the patient is on gastric suction, all sulfonamides are administered intravenously in dosages adequate to maintain a level of from 8 to 12 mgm. per cent in the blood. Sodium sulfadiazine is the drug of choice and usually not more than 5 gm. per day is required.

The drinking of water is encouraged as soon as the patient returns to bed.

Elevation of the foot of the bed is employed for the first 24 hours to prevent shock and encourage the drainage of mucus from the respiratory tract.

Catheterization is required more frequently after spinal anesthesia and is done if the patient has not voided by the end of the first day.

Patients are placed in a wheel chair for 15 minutes on the first postoperative day and more frequently and for longer intervals thereafter. They walk without aid by the sixth or seventh day.

The diet is not resumed until the Levine suction tube has been withdrawn.

Enemas are not administered until the fifth or sixth postoperative day and then only in small amounts.

CHARLES BARON, M.D.
Mason J. W., III: Surgery of the Colon in the Forward Battle Area. *Surgery* 94:5 8 534

About one-half of the diameter of the entire right colon both flexures and a portion of the rectosigmoid is found to lie behind the peritoneum. In explorations and for the relief of tension on colostomies, the simple procedure of mobilizing these areas should be kept in mind. The lateral attachments of these portions of the colon are avascular, the mesentery coming in from the medial aspect, and they can be incised with impunity the colon being displaced medially.

Injuries of the right colon from the ileocecal junction distally which necessitate the removal of the cecum and any portion of the right colon are a problem because of the difficulty in dealing with the transected end of the terminal ileum. The open end of the ileum is, of course, a problem because of the erosive action of its contents, if they are allowed to drain out into the abdominal wall. There are four ways of handling this problem

1 A primary anastomosis may be performed between the terminal ileum and the cut end of the transverse colon (end to side ileotransverse colostomy) the blind end of the colon being turned in by suture.

2 An end to side primary anastomosis may be performed, the blind open end of the colon being brought out of the abdomen through a stab wound as a safety valve.

3 A lateral anastomosis may be performed between the ileum and the colon, both ends (ileum and colon) being brought out distal to the anastomosis as a double barreled spur colostomy.

4 The ileum and colon may be exteriorized as a long sutured double barreled ileocolostomy constructed for the purpose of early crushing of the spur with a clamp.

The first three procedures are objectionable since they necessitate a primary anastomosis in an unprepared colon. This is too dangerous. The fourth alternative is the one which has been used with good results. Early crushing of the spur at the base of the hospital within two or three weeks or earlier crushing at the front preferably the former will prevent any irreparable skin erosion. Postoperative care consisting of the administration of vitamins the correction of dietary deficiencies and the restoration of the blood chemistry to normal levels will play a large part in such treatment.

All exteriorizations should be made through separate stab wounds and not through the upper or lower poles of an exploratory incision. Often it has been convenient to bring a colostomy out through a debrided wound of entrance or exit, but this is avoided if possible. There is a place for tube colostomies in the management of single perforations of the cecum. However in general, it is preferable to exteriorize such wounds. The evacuation of the patient and the change of management that he is subjected to may result in periods of time during which the proper attention cannot be paid to the tube.

A tube may be of advantage in diverting the stream of fecal contents in an ileocolostomy or it may be used in a colostomy but its period of usefulness is not very long as leakage soon occurs around the tube.

Questionably viable areas of colon due to a damaged mesentery or to trauma to the wall of the gut proper should be exteriorized.

The management of war wounds of the colon differs materially from the management of lesions of the colon generally encountered in civilian practice. The excellent results obtained in civilian practice by the performance of primary anastomosis on the properly prepared colon permits the immediate re-placement of the anastomosed portion in the general peritoneal cavity. In dealing with emergency war surgery it is believed that all colon injuries should be exteriorized and that no primary anastomosis is warranted.

BENJAMIN GOLDMAN, M.D.

Pierpont R. Z. Peterson F. R. and Dullin J. W.: *Operative Results of Surgery of the Colon for Neoplastic Disease* *Surgery* 1945 18 541

The operative results of colon surgery for neoplastic disease covering the period between January 1 1937 and December 31 1944 in the State University of Iowa Hospitals Iowa City are reviewed and the results of treatment tabulated. Exploration was carried out in 221 patients and of these 117 had resection of the colon a resectability rate of 53 per cent.

Among the 221 patients operated upon there were 46 deaths a mortality of 20.5 per cent. Among 117 resections 23 deaths occurred a mortality rate of 19.6 per cent. Among 81 patients in whom a palliative operation was done for the relief of obstruction there were 17 deaths a mortality rate of 20.9 per cent. Altogether there were encountered 122 lesions of the left side and 82 lesions of the right side.

The authors report that an increasing number of resections with immediate end to end anastomosis are being performed in their clinic and point out that there is no one operative procedure which can be applied to all neoplasms of the colon.

WALTER H. ADLER M.D.

Miles, W. E., Gordon Watson C., Milligan E. T. C. and Corbett R. S.: A Discussion on the Management of the Permanent Colostomy. *Proc. A Soc. M. Lond.* 1945 35 695

Miles observed that very few doctors appreciate the value of the daily wash-out of the colon for controlling bowel movements. There is no doubt what ever that bowel action can definitely be controlled by means of a daily wash-out with 1½ pints of plain water at a temperature not exceeding 80 F. as determined by the thermometer. This is repeated if necessary. Should the temperature exceed 80 F. inertia of the muscular coat of the colon is produced which results in retention of part of the fluid used and several hours may elapse before the muscular inertia disappears. A plain wash out if properly administered can be relied upon to clear the colon completely of its fecal contents. It sometimes happens that difficulty is experienced in introducing the tube into the colon to the required extent. As a rule this is due to the attempt to introduce the tube when the patient is sitting up or standing, or when he raises his head in order to pass the tube under guidance of the eyes and puts his abdominal muscles on the stretch. In order to pass the tube the patient should be recumbent with the abdominal muscles completely relaxed. One of the causes of difficulty in passing the tube is acute angulation of the colon at the point where it changes direction and passes forward to the opening in the anterior abdominal wall. Such angulation can be entirely prevented by mobilization of the terminal portion of the descending colon.

A weak spot in the abdominal wall has been created by the passage through it of the loop of pelvic colon destined for the formation of the colos-

tomy. In order to afford support to the weakened abdominal wall a well fitting colostomy belt must be obtained. On no account should the patient allow himself to be persuaded to have a rubber bag attached to the cup of the belt to act as a receptacle for feces. Such a bag creates suction and in the course of time the part of the colon which is proximal to the stoma is turned inside out and extruded through the stoma. It is important that the belt should be worn continuously when the patient is up and about.

The stoma of a colostomy should be prevented from becoming stenosed by systematic dilatation. For this purpose the patient must be taught to pass his index finger to its full extent through the stoma. He must also be instructed how to pass his finger to its full extent before flexing the distal joint. As soon as the colostomy wound has healed firmly the index finger of the left hand (if the stoma is on the left side) should be passed through the stoma every day for a month then once a fortnight for two months and finally once a month for six months, when it will be found that the tendency to contract has ceased.

GORDON WATSON states that in order to secure a good working colostomy it must be well fashioned and first of all it is essential to secure a good spur by keeping the bowel outside of the abdominal wall for at least three weeks by the use of a glass rod or other means it is also necessary to avoid undue tension on the mesentery. The stoma should be well clear of the anterior superior iliac to avoid interference with the belt. The size of the opening in the abdominal wall should be just large enough to allow a finger to pass down on either side of the glass rod. An ellipse of skin should be removed to prevent subsequent contraction which is apt to cause recession of the opening. All cups and bags should be avoided a plain celluloid disc is all that is needed. Some patients find this unnecessary and wear only a singlet.

The colostomy is trained to act only when it is washed out, which is done at the same time each day with plain tepid water without soap and a flexible tube (size 14) which is passed up as far as possible with great care. The fluid is run in slowly preferably by funnel.

When this is carefully carried out at the same time each day the colon learns to respond in an automatic way and many victims carry on their work with little disability. In a small percentage of cases the colon will behave as if the stoma was the rectum and act regularly and automatically without a wash-out with or without a mild aperient. If there is a tendency to looseness disastera may occur.

GABRIEL stated that after a colostomy (terminal loop, left iliac, or transverse) has been established, we have to decide if the bowel is to be allowed to act naturally or whether the wash-out regime is to be adopted. He is opposed to the wash-out regime for colostomies for the following reasons:

1. It is unnecessary because the great majority of colostomy patients have good intestinal function.

and with reasonable care and discretion in diet they achieve a satisfactory and regular rhythm with formed colostomy actions.

3 It is harmful because it is not natural for the colon to have a solution thrust into it daily be it plain water, normal saline solution or soap and water. Colonic lavage for prolonged periods induces a chronic catarrh of the colon with a hyperemic mucosa, a contracted bowel lumen, and the excessive formation of mucus. In other words this routine induces a state of catarrh and irritability in the colon which is exactly contrary to what is desirable after a colostomy.

3 It is dangerous because the passage of a tube up the colostomy may lead to perforation, peritonitis, and death. In hospital work a colostomy wash-out is rarely necessary in the immediate postoperative period and usually the insertion of a glycerine suppository serves the purpose equally well.

MILLIGAN says that there is no surgical substitute for the rectum. The rectum is under the control of the patient for storage and ejection. A colostomy can never be trained to have conscious sensations or voluntary powers similar to the rectum. The crude muscles of the abdominal wall cannot act like the specialized rectal and anal muscles in retention and expulsion.

The same rhythm or regularity of bowel action can be attained with a colostomy as with a normal rectum that is, the 24 hour rhythm for in all of us with or without a rectum this rhythm depends upon the colon.

This author states, "We cannot control the colostomy but it can be controlled." He also maintains that Nature's standard of one and only one motion a day can be reached with a colostomy. How then are we to attain but one bowel action a day for a colostomy?

The answer is by routine morning wash-out if the rhythm does not come naturally after a short trial. A bowel completely emptied by a wash-out followed by a morning bath and clean dressings enables a man to face the day and his fellows without handicap.

The bowel action is likely to be regular after the removal of the rectum if the daily evacuation before colostomy was by rhythm rather than by feeling.

CORBETT considers the subject under two headings: (1) the part played by the patient and (2) the part played by the surgeon.

The patient wants a regular evacuation of the bowel and freedom from the anxiety of leakage. He wishes to be able to carry on his daily life in much the same way as he was accustomed to do before operation. His part in the management can be carried out in one of two ways:

1 Training the bowel to act regularly of its own accord in order to have a daily action.

2 Washing out the bowel regularly every day.

In the part played by the surgeon it is of great importance that certain essentials should be remembered in the formation of the colostomy and in the management of the postoperative period. This

will lead to easy management and avoid complications.

1 There is a choice of three positions for the stoma: at the left ilium, at the rectus sheath and possibly at the epigastrium. Colostomies in all of these positions appear to work equally well.

2 The formation of an adequate spur is essential. A glass rod is popular, easy to apply and very satisfactory. The rod or a substituted rubber tube should remain in position for 3 or 4 weeks.

JOHN J. MURPHY, M.D.

BUTTS, J. B., and CONLEY, J. E.: Perinephric Abscess; Report of 3 Cases Simulating Acute Appendicitis. *U. S. Army Med. Bull.* 1945 45 1087.

In the differential diagnosis of any abdominal pain, one should consider perinephric abscess, although it is uncommon. The syndrome of obscure fever with pain in the right flank and abdomen due to perinephric abscess may be easily confused with acute appendicitis and lead to a deleterious appendectomy. The authors report 3 cases simulating acute appendicitis.

A perinephric abscess is an infection outside of the kidney capsule with resultant necrosis of the perirenal connective tissue and suppuration in the renal fossa. The cases presented were simple perinephric abscesses as contrasted to complicated abscesses associated with pathological kidney changes. Authorities differ in opinion as to whether all perinephric abscesses are secondary to some infection in the kidney.

Abdominal exploration may be undertaken when the clinical picture of perinephric abscess simulates acute appendicitis, and when urinary abnormalities are absent as they were in these 3 cases. Often there is a history of a skin infection or a severe upper respiratory infection several days or even weeks before the onset of the first symptoms. In these 3 cases no such history was elicited, although in case 3 a severe back injury occurred prior to the onset of the symptoms.

Anorexia, fatigability and night sweats are early complaints, followed usually by chills and fever. Pain in the right flank radiating to the costo-vertebral angle and to either of the upper or lower quadrants may be the earliest specific complaint. The 3 patients in this report all had pain in the right flank radiating to the right lower part of the abdomen. Simeone reported that lesions involving the perinephrium anteriorly cause pain in the right lower abdominal quadrant. Atcheson reported that 16 of 117 patients with perinephric abscess presented with complaints of lower abdominal pain, and 8 of the 16 had associated abdominal rigidity. Urinary symptoms are uncommon in cases of simple perinephric abscess.

On physical examination the patients are acutely ill and may show evidence of weight loss if the disease is prolonged. Most of them have tenderness in the right flank, and spasm and swelling are often present also. Simeone reported 3 of 34 cases with

tenderness present in the right lower quadrant only. Scoliosis with the concavity toward the affected side due to paravertebral muscle spasm is a prominent sign of perinephric abscess. Secondary inflammatory involvement of the psoas muscle may cause the patient to hold the hip flexed. Motion of the hip then causes severe pain.

Positive x ray signs such as obliteration of the psoas shadow, enlargement of the kidney shadow, concavity of the spine toward the side of the lesion, decreased movement of the kidney and diaphragm on respiration and displacement or distortion of the kidney or ureters may help to make the diagnosis. Only 45 per cent of the cases show positive x ray signs, so too much emphasis should not be placed on negative findings.

In simple perinephric abscess the urine is normal unless there is some kidney abnormality. The presence of albumin and white blood cells in the urine indicates gross involvement of the kidney itself. The staphylococcus aureus is most commonly cultured from simple perinephric abscesses while in complicated perinephric abscesses secondary to renal calculus and infection the *Escherichia coli* is found. Chemotherapy before operation may be responsible for negative cultures in some cases.

Prompt surgical drainage is the treatment of choice and leads to dramatic improvement in the symptoms. If the perinephric abscess is complicated a primary or secondary nephrectomy may be necessary. Usually the disease is far advanced when the diagnosis is made, 12, 7 and 8 days respectively, intervened between the admission of the patient and operation in the reported cases.

There was no mortality in the reported cases of simple perinephric abscess while mortalities of from 14 to 50 per cent were encountered in cases of complicated perinephric abscess.

ROBERT R. BLOOM, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Nigam, K. S., and Sircar, J. K.: An Additional Test Helping in the Diagnosis of Chronic Cholecystitis. *Ind J Surg* 1945 7 95

Patients with chronic cholecystitis show marked cholesterol retention. The authors estimated the cholesterol in separated serum for which they used the colorimetric method. In most of the cases the estimation was done on an empty stomach in order to eliminate the dietetic factor. The estimation was carried out on 86 cases.

The minimum figure was 73 mgm. in a child aged 10 years and the maximum was 350 mgm. in an old man of 60 suffering from an enlarged prostate with secondary vesical calculus therefore the average was 145.9 mgm. The table shows the amounts of serum cholesterol within certain limits in the cases. In this series of cases the reading is higher than that found in the whole blood in India by other workers but it approaches the readings in other countries.

Serum Cholesterol	N of cases	Percentage
Below 100 mgm.	4	4.7
Between 100 and 119 mgm.	13	17.4
Between 120 and 139 mgm.	35	40.1
Between 140 and 179 mgm.	17	18.8
Between 180 and 200 mgm.	10	11.6
Between 200 and 220 mgm.	5	5.8
Above 220 mgm.	2	2.3

The ingestion of food rich in cholesterol for some time has been known to produce an increase in the blood cholesterol. It has been the aim in the present work to study the changes in the amount of cholesterol in the blood of human beings after a single ingestion of fatty diet and to compare them with the changes so obtained in patients with cholecystitis. At the very outset it may appear that the test of giving fatty diet may not be safe in cases of cholecystitis but fortunately in this series of cases no complications or trouble occurred. The diet which has been prescribed does not contain such an excess of fat that it upsets the patient, but it has enough cholesterol in it to make the estimation desirable. The test need not be done in cases of acute cholecystitis in which the diagnosis is obvious. It is certainly very helpful in the obscure and chronic cases. In acute cases the test should be applied after the acute symptoms have subsided and the patient is allowed solid diet.

It was found that 11 of 12 cases showed the maximum rise in the cholesterol level was below 80 mgm. only in 1 case the figure was high. The average was about 52 mgm. Seven cases of gall bladder disease could be studied and of these 6 were cases of chronic cholecystitis and 1 was a case of cancer of the gall bladder as proved on the operating table. In 3 cases the cholesterol metabolism could be studied both before and after operation and it was noticed that the rise in the level was not so high after the operation of removal of the diseased gall bladder. If tables are compared after the diseased organ is removed from the body in cases of cholecystitis the metabolism curve again becomes low like that of other normal people. It can be judged by comparing the graphs of patients who have been operated upon. If the rise of cholesterol is between 100 and 150 mgm. the case is probably one of cholecystitis, but if the rise is more than 150 mgm. one should be inclined to think it is a case of cholecystitis and this adds to the existing methods of confirming the diagnosis of chronic cholecystitis.

By comparing the tables one is forced to think that the marked rise in the level of the serum cholesterol in the table shown herewith is certainly due to the diseased condition of the gall bladder. In all of the first 6 cases the rise was more than 100 mgm. the minimum being 106 mgm. the maximum 188 mgm. and the average 161.5 mgm. The seventh case was that of a cancer of the gall bladder and in this the rise was only 75 mgm. although the fasting serum cholesterol was 300 mgm. and was due to jaundice. It is only in the chronic inflammatory conditions of the gall bladder that a marked rise in the level of

serum cholesterol occurs in the case of a new growth this was not noticed.
CHARLES BARON, M.D.

Ottoman, R. E., and Baker, J.: Metastatic Staphylococcal Infection of the Gall Bladder. *West J Surg* 1945 53 361

The authors report 2 cases of empyema of the gall bladder as a complication of simple superficial staphylococcus infections. One was secondary to a felon of the thumb and the other followed a sac excision of boils. Staphylococci were cultured from the gall bladder in each case. One gall bladder contained stones but no stones were found in the other.

In each patient the diagnosis was difficult because of red cells, pus cells and staphylococci in the urine. In 1 patient a severe pyelonephritis intervened between the boils and the cholecystitis. In the other a peritoneal infection was suspected but it was not proved.

Cholecystostomy was done in each case and resulted in recovery.
EARL O. LATIMER, M.D.

Milgram, P. L.: The Cystic Duct in Biliary Lithiasis (Il condotto cistico en la litiasis biliar). *Prensa med. argent* 1945, 31 2149

The author describes the normal anatomy and histology of the cystic duct and variations of the position of the duct under pathological conditions.

Mucosities of the cystic duct may be caused by an abnormally high resistance of the sphincter of Oddi, increased mucous secretions of the extrahepatic ducts, dilatation and hypertrophy of the wall of the cystic duct.

The cystic duct may be entirely absent and in such cases the gall bladder empties itself directly into the common duct. The cystic duct may also form a junction with one of the hepatic ducts, usually the right. A double cystic duct has also been described. The cystic duct may be adherent to Hartmann's pouch. Cases of primary carcinoma of the cystic duct have been reported in the literature.

A dilatation of the distal portion of the cystic duct comparable with a river estuary may be the sequel of stenosing inflammation or functional disorders of the sphincter. Such formation is of practical importance because a ligation of the cystic duct may produce traction on the opposite wall of the common duct and lead to an interruption of the biliary flow.

Under normal circumstances the cystic duct forms an acute angle with the hepatic duct. As a result of a gallstone formation this angle may become more pronounced and interfere with the bile flow to the gall bladder. Paroxysmal crises accompanying the resulting anatomofunctional hepatic syndrome may become quite serious and may produce jaundice. Sclerosis of the biliary ducts in such cases distorts the normal anatomy and there is great danger of inadvertent ligation of the right branch of the hepatic artery.

Clinical diagnosis of primary carcinoma of the cystic duct is impossible. As a rule the condition is mistaken for cholelithiasis.

Biliary fistula of the cystic duct after an operation is usually due to a stone formation between Heister's valves. Occasionally a biliary phlegmon of the abdominal wall, without a stone formation, may lead to the formation of a fistula of the cystic duct.

Lithiasis of the cystic duct is a rare condition. Intermittent is observed in about one-third of all the cases.

An inflammation of the stump of the cystic duct following cholecystectomy without a stone formation is relatively frequently responsible for postoperative pains.

Neuromas in the wall of the cystic stump may be responsible for postoperative pains. A dilatation of the stump of the cystic duct may be followed by a concomitant dytonia of the sphincter of Oddi. Some times such conditions require a choledochoduodenostomy.

In selected cases abnormalities of the lumen of the common duct may be corrected by the implantation of the cystic duct into the duodenum in order to side track the bile flow. The operation may be considered in some cases of incipient stenosing pancreatitis.

The author advocates preservation of the cystic duct after cholecystectomy not only to facilitate operative cholangiography but also to create a safety valve in cases in which an incomplete obstruction of the distal third of the common duct is present.

JOSEPH K. NARAY, M.D.

Dameshek, W., and Miller, E. B.: The Megakaryocyte in Idiopathic Thrombocytopenic Purpura, a Form of Hypersplenism. *Blood J* 1946 946 27

The megakaryocytes of the sternal bone marrow were studied at biopsy in 12 cases of idiopathic thrombocytopenic purpura and compared with those of 10 normal individuals, of 5 cases of thrombocytopenic purpura associated with various types of splenomegaly and of a large group of miscellaneous hematological conditions associated with a reduction in platelets including leucemia.

Megakaryocyte counts expressed in terms of a million nucleated red cells and differential counts of megakaryocytes were made. The megakaryocytes were classified as megakaryoblasts, promegakaryocytes and mature forms, and were further subdivided into those showing granular platelet production, degenerated forms, and mitoses.

In the normal individuals, not more than 300 megakaryocytes per million nucleated red cells were present, and an average of 68.6 per cent showed platelet production. In the case of acute idiopathic thrombocytopenic purpura although the platelets in the circulating blood were rare, the megakaryocytes were increased being present in a proportion of from 366 to 743 per million nucleated red cells. However platelet production was greatly diminished and found in from only 8 to 19 per cent of all megakaryocytes. Following splenectomy, there was a striking increase in the platelet production, which was now present in from 69 to 85 per cent of all the cells, and the large masses of new platelets in the

marrow were often very striking. In the cases of chronic idiopathic thrombocytopenic purpura the megakaryocytes were considerably increased over the normal values but showed great diminution in platelet production following splenectomy. Extreme degrees of platelet production from the megakaryocytes took place. In splenomegaly of nonleukemic origin (cirrhosis, splenic vein thrombosis, Gaucher's disease, Felt's syndrome) the megakaryocytes were somewhat increased but platelet production was normal. In aplastic anemia, lymphosarcoma, acute leucemia and other diseases invading or destroying the bone marrow, the megakaryocytes were conspicuously reduced, the few remaining cells being of normal morphology.

The findings of increased megakaryocytes and greatly diminished platelet production in the marrow before splenectomy and the striking increase in platelet production after splenectomy indicate a definite pathogenetic relationship of the spleen to the disease. Idiopathic thrombocytopenic purpura is probably a form of hypersplenism (splenic thrombopenia) in which, through a possible hormonal mechanism, the megakaryocytes of the bone marrow are inhibited from normal platelet production and delivery. The marrow findings in idiopathic thrombocytopenic purpura are sufficiently characteristic to be of diagnostic value in differentiating the disease from leucemia and other conditions associated with a low blood platelet count. Etcheverry, M.: Postoperative Eventration through the Anterolateral Abdominal Wall (La eventración postoperatoria en la pared anterolateral del abdomen). *Rev. méd. quir. pos. fem. B. Afr.*, 1945, 13, 395.

The frequency of eventration remains approximately the same from year to year; it occurred in about 2.5 per cent of all laparotomies according to the author's statistics. Three main factors responsible for eventration must be considered: (1) organic deficiency of the patient, either local or general, (2) technical errors, and (3) postoperative complications which interfere with normal restitution of the tissues.

Four conditions of the abdominal wall can be distinguished in the discussion of disruption of the abdominal wound: the hypertonic and hypotonic abdomen and the strong and weak abdominal wall.

Eventration occurs mostly in the anterolateral portion of the abdomen at the site of the fusion of the superficial and deep aponeurosis.

As far as the operative technique is concerned, 3 points are essential: (1) adequate exposure, permitting easy access and manipulation of the organs to be operated on, (2) proper selection of the zone of the abdominal wall, allowing perfect reconstruction, and (3) selection of the direction of the incision with regard for the integrity of the muscular fibers and nerves.

A transverse incision seems to be logical because it is parallel to the blood vessels and nerves. Particular care must be exercised when catgut is used as suture material.

The author mentions three frequent causes of disruption of the abdominal wall: (1) a subcutaneous or subaponeurotic hematoma attributable to insufficient hemostasis, (2) infection of the wound, and (3) the introduction of a drain into the abdominal cavity. The irritating effect of a foreign body such as a drain is intensified by contamination of the abdominal wound by infected fluids escaping from the peritoneal cavity.

The author prefers a double knot to a triple knot because of the facility of tying and a lesser amount of foreign body left in the wound. If a triple knot is used, catgut is usually tied twice in the same direction and the last time in the opposite direction. The author prefers tying the knot in alternating directions. He also maintains that a continued suture approximates the tissue better than interrupted sutures. JOSEPH K. NARAT, M.D.

Colp, R., and Druckerman, L.: Subtotal and Palliative Gastrectomy for Chronic Gastric Ulcer. *Surgery*, 1945, 18, 573.

A series of 42 consecutive patients suffering with chronic gastric ulcer treated surgically is presented. The duration of the disease varied from several months to 40 years. The patients were admitted to the surgical service only when the pain was becoming more severe despite adequate treatment, when an intractable pyloric stenosis was evident, when hemorrhages had become recurrent, and when the presence of a carcinoma was suspected. In the series of 42 cases of benign ulcer, the roentgenologist reported 3 cases as being highly suggestive of neoplasia. Of 22 cases in which the gastroscopist could visualize gastric ulcerations, 5 were pronounced malignant but were subsequently proved to be benign. An absolute achlorhydria was present in 12.

The preoperative preparation of such patients, many of whom are in poor general condition, is outlined. At present the authors prefer continuous spinal anesthesia combined with sodium pentothal intravenously since it provides the best relaxation and exposure with a minimal amount of retraction. Exploration is carried out through a median epigastric incision and the operation of choice is subtotal gastrectomy of the Hofmeister type. If the lesion is so massive that resection appears impossible, preliminary jejunostomy seems a logical procedure to put the stomach at partial physiological rest and cause regression in size of the ulcer so that partial gastrectomy may be performed several weeks later with comparative ease and safety. The stomach is usually removed in a retrograde manner, and antecolic anastomosis using a short proximal loop of jejunum about 6 inches long is performed.

In 9 cases in which either a very high gastric resection had been performed or in which a marked

preoperative dilatation of the stomach increased the possibility of postoperative gastric atony a complementary jejunostomy for alimentation was done. There were 6 cases in which the antrum and pylorus were removed, but the ulcer was left *in situ*. The so-called palliative gastrectomy has not had wide application and has one major disadvantage—the lesion which is not removed may possibly be carcinomatous. On the other hand removal of the antrum and pylorus of patients suffering from gastric ulcer almost always results in anacidity so that recurrent gastric or gastrojejunal ulcer is almost unknown.

The indications for palliative gastrectomy in this series were penetrating ulcer high on the lesser curvature or ulcers juxtaesophageal in location. The general physical condition in 4 patients was so poor that an excessively high resection necessary to remove the ulcer would have been extremely hazardous.

The postoperative course and complications are described. In the series of 49 consecutive gastrectomies for gastric ulcer there were 2 deaths.

JOHN L. LONGQUET, M.D.

Poth, E. J., Ross, C. A. and Fernandez, E. B.: An Experimental Evaluation of Sulfasuxidine and Sulfathiazidine in Surgery of the Colon. *Surgery* 1945 18 529.

The study made by these authors shows sulfasuxidine and sulfathiazidine to be valuable adjuncts in surgery on the colon of the dog. The indications are that the so-called aseptic methods of anastomosis should be used whenever possible, but it is evident that an open technique may be undertaken with a considerably increased degree of safety. These observations support the satisfactory results obtained when man is treated in a similar manner.

The reaction, as revealed by the amount of edema of the omentum adherent to the line of suture, is significantly less when the bacterial flora is modified by the administration of the drugs. The most clearcut evidence of the value of these drugs is revealed by the results which followed the method of open anastomosis, wherein no effort was made to prevent fecal soiling of the operative field. Even though the degree of spillage was much greater following the administration of sulfasuxidine because of the semifluid nature of the contents of the bowel, there was a striking difference in the operative mortality and morbidity. Forty-three per cent of the control animals died of generalized peritonitis due to disruption of the line of suture. One hundred per cent of the control animals showed gross leakage at the line of suture. These observations are in contradistinction to absence of death and lack of gross leakage through the suture line when the animals had received sulfasuxidine and sulfathiazidine. Furthermore in the control experiments there was acute inflammation and little evidence of healing and repair by the fifth postoperative day. Following drug therapy the inflammation had subsided and

the tissues had undergone orderly repair and healing.
BENJAMIN GOLDMAN, M.D.

Patton, E. F.: Proctological Problems of the Pediatrician. *J. Pediatr.*, S. Louis, 1945 27 532.

The etiology of constipation, painful defecation, frequent small stools, and bleeding per rectum in infancy and childhood is often an abnormality or a disease of the anus or rectum which can be determined by proctologic examination.

A frequent cause of constipation in early infancy is an incomplete dissolution of the membranes between the blindgut and the proctodeum. This may be manifest at birth, but may not develop to a degree of marked obstruction for days or even weeks. The opening may be adequate at first, but as time goes on, folds of mucosa of the segment of rectum above the constriction overlap across the lumen, thus forming a valve. A stenosis, in the form of a diaphragm or ring of tissue, can be overcome by one or more gentle dilations with a lubricated, rubber covered finger.

The usual cause of painful defecation is an anal fissure or an area of proctitis. In an infant or small child an electric otoscope using a large speculum serves as a useful proctoscope. Anal fissures are readily visible. Proctitis is seen as a red, congested area of mucosa contrasting with the pale pink, normal tissue around it. A regimen to produce small soft stools is necessary to heal a fissure or proctitis. This involves the establishment of two regular toilet times daily: the occasional use of a suppository or enema, the intake of generous quantities of water, stewed fruits and vegetables, the temporary use of combinations of agar and mineral oil by mouth, and anesthetic ointments locally. The healing of fissures and proctitis is aided by the topical application of silver nitrate.

Frequent small but otherwise normal stools may be caused by anal fissure, proctitis, or a local dermatitis. The latter may be due to a fungus infection, pinworms, scabies, cryptitis or papillitis. The treatment of this complaint is dependent upon the cause.

The many causes of bleeding per rectum are well known. The causes of rectal bleeding visible through the proctoscope are fissure, proctitis, polyp, or ulcer (nonspecific or amebic).

Prolapse of the rectum may be caused by a polyp, but it is usually due to a redundant mucous membrane. In the immediate treatment concern should not be so much for prompt reduction as for permanent retention after reduction. If prolapse is allowed to persist for hours, or even until spontaneous reduction with simple recumbency takes place, the resulting edema and local submucous reaction is helpful in producing thickening and fibrous tissue which will help in permanent retention if the stools can be kept small and smooth enough to pass easily while mucosal edema is subsiding. Various methods are proposed for maintaining reduction, such as continued recumbency, elevated hips, or

strapping the buttocks together with adhesive tape. The anti-constipation regimen as outlined before must be instituted concurrently. If conservative treatment fails to prevent recurrences a sclerosing solution may be injected in the submucous tissues.

Although megacolon is not primarily a proctologic problem, some cases can be relieved by systematic rectal dilatation with graduated dilators.

Perirectal abscess, fistula in ano and hemorrhoids in childhood are managed as in later life.

ERNEST E. ARNHEIM, M.D.

Alecha J. M., Carpanelli, J. B. and Ferreira J. A.: Amebic Abscess of the Liver Opening into the Peritoneal Cavity (Absceso amebiano hepático abierto en cavidad peritoneal). *Rev. As. Méd. Argent.* 1943 59 1043

Amebic abscess of the liver is the most frequent localization of amebiasis outside of the intestine. An analysis of 14,907 cases of amebiasis showed hepatic abscess clinically in 4.86 per cent but autopsy showed it in 36.6 per cent.

The diagnosis is often not made until perforation occurs although a careful study of the history should give indications of the true diagnosis. X-ray examination may show malformation of the liver especially of its diaphragmatic surface and may also show peritoneal effusion. Rectosigmoidoscopy may be useful in showing dysenteric ulcers. In 90 per cent of the cases the pus in the abscess is aseptic. Amebae are much more apt to be found in tissue curetted from the walls of the abscess.

A case is described in a man of 37 years in whom the diagnosis was not made until operation although he had a rather typical history. He had been treated in a clinic 3 years before however and

neither laboratory nor roentgen examination had given any indication of the true diagnosis. When he was admitted with the picture of acute peritonitis a diagnosis of perforated acute cholecystitis was made. Operation showed the true condition and the abscess was evacuated and emetin treatment begun. The amebae disappeared from the feces after the first series of emetin and the patient made an uneventful recovery.

Although the pus of the abscess was aseptic the diagnosis of its amebic character was made from the lack of any history or evidence of pyogenic infection, the macroscopic appearance of the abscess and its contents, the relative seriousness of the case and the slight postoperative peritoneal reaction, the presence of the vegetative forms of amebae in the feces after operation, and the course of the disease.

Some surgeons use emetin intraperitoneally during operation, but the authors do not believe there is any logical indication for its use in this way.

AUDREY G. MORGAN, M.D.

Brunschwig, A.: Radical Resections of Advanced Intra Abdominal Cancer. *Ann. Surg.* 1945 122 923

Progress in supportive treatment of the surgical patient permits of the extension of radical surgical attack upon advanced abdominal cancer. Experiences in a series of 100 patients revealed that effective, albeit in some instances brief palliation was afforded in 35 per cent and an appreciable and prolonged palliation was achieved in an additional 15 per cent of the series. Given adequate conditions, a more radical attitude in the surgical treatment of advanced abdominal cancer would appear justifiable.

CHARLES BARON, M.D.

UTERUS

Curtis, A. F.: *Observations on Certain Rheological Properties of Human Cervical Secretion*. *Proc. R. Soc. B. Lond.* 1945 39 1

Cervical mucus like most other secretions of the body is not a true fluid because it does not flow at a steady rate under constant pressure. Further more when pressure is increased the rate of flow does not increase proportionately. Such secretions are complex systems characterized by properties such as anomalous viscosity, elasticity, flow-elasticity, Spinnbarkeit and adhesiveness. A study of such physical properties is called rheology.

Experimental evidence and numerous clinical observations suggest that the rheological properties of human cervical mucus undergo a cyclic variation in the menstrual cycle and furthermore bear direct relation to ovulation to penetrability of cervical mucus by spermatozoa and to pregnancy.

This author has directed his attention primarily to the study of two hitherto unrecognized rheological properties of cervical mucus—namely, flow elasticity and Spinnbarkeit. When a material showing flow elasticity is caused to flow along a tube and the pressure is suddenly released the material recoils towards its original position. This property is accurately measured in the meniscoscope, an instrument which consists essentially of a graduated glass capillary tube. One end of the tube is open, the other fits tightly on to a syringe. A small side tube for the control and sudden release of pressure is interposed between the syringe and the main tube.

Spinnbarkeit is the capacity of liquids to be drawn into threads. The most suitable English term now available is "viscosity". It is a property of cervical mucus and is capable of accurate measurement. The test is carried out by drawing away a cover slip placed on a blob of mucus and measuring in centimeters the thread thus produced.

The author stresses the following points as a prerequisite of interpretation of result:

1. The cervix must be healthy, with no pathological tear, marked erosion or endocervicitis.
2. Contamination with blood should be reduced to a minimum.
3. The specimen must be collected from the cervical canal not from the vaginal vault or from the external cervical os.
4. Neither douching nor coitus must have taken place during the 48 hours preceding collection.
5. No antiseptics should be used in collecting the sample.
6. The test for flow-elasticity (elastic recoil) should be performed within 30 minutes of collection of the sample.

The cervical mucus of 26 women showing normal menstrual cycles was studied. Seven of these women

were seen more than once, 3 were studied for at least one complete cycle and 2 became pregnant during observation. Flow-elasticity and Spinnbarkeit were measured. The amount of mucus secreted, the macroscopic appearance and the number of leucocytes contained in the specimen were also noted. These properties were carefully correlated with the time of the menstrual cycle or pregnancy and they supply two new rheological tests.

A rheological test for ovulation in woman is described. The sample of cervical mucus is runny and homogeneously translucent. Flow-elasticity and Spinnbarkeit are maximum. The cellular content is minimal. At this time penetrability and longevity of spermatozoa are greatest.

A rheological test for pregnancy in woman is described. The sample of cervical mucus is thick and homogeneously opaque. The mucus is difficult to draw into the meniscoscope and there is almost complete absence of flow-elasticity and Spinnbarkeit.

These rheological phenomena and tests should prove of value in the recognition of ovulation and anovulatory cycles in the investigation and treatment of some forms of sterility (cervical hostility) in various types of ovarian dysfunction, and in application as accessory tests for pregnancy.

L. J. MITCHELL M.D.

Curtis, A. F.: *Hypertrophy of the Uterus*. *Br. J. Obst.* 1945 50 742.

The usual symptoms of hypertrophy of the uterus are prolonged or excessive menstruation, pelvic pressure with more or less aching discomfort, and increased vaginal discharge.

Examination reveals an enlarged uterus which is usually heavy, often retrodisplaced, and difficult to differentiate on bimanual examination from adenomyosis of the uterus or diffuse enlargement from deeply buried myomas. Differentiation from carcinoma of the body of the uterus is sometimes difficult, occasionally even after examination of uterine curettings in the cases of hypertrophy with marked endometrial hyperplasia.

Histological diagnosis of the various types of uterine hypertrophy is facilitated by differential stains. With routine hematoxylin and eosin stain, enlarged and thickened blood vessels and the amount of perivascular connective tissue are readily recognized but accurate determination of the relative proportion of connective tissue and muscle cells is not simple. A trichrome stain similar to the Masson stain helps to solve this difficulty.

The more enlarged uterus is studied the more apparent it becomes that various gradations of hypertrophy are encountered in most instances and that pure subinvolution or true diffuse hypertrophy or hypertrophy due solely to metritis or to endocrine disturbance is unusual.

Curetage may be required for differential diagnosis, and strangely enough, it is sometimes beneficial. If more important surgical intervention is required, one should hesitate to perform corrective operations for uterine displacement in these cases unless childbearing is an important issue. Removal of the offending organ by subtotal or complete hysterectomy is the procedure of choice.

EDWARD L. CORNELL, M.D.

Waterman, G. W., and DiLeone, R.: Treatment of Carcinoma of the Cervix with Interstitial Radium Needles at the Rhode Island Hospital. *Am. J. Obst.* 1945 50 483

The authors report first the 10 year survival rates on 309 cases from 1926 through 1933 which were previously reported for five year survivals second they add a new series of 198 cases which passed through the Clinic from 1934 through 1938 and third they review the total of 507 cases from 1926 through 1938.

An improvement in the results in the last three years from 1936 through 1938 in 127 cases is shown.

The effect of age on the extent of growth when first seen (clinical stage) and on the prognosis (five year survival rate) is shown.

The incidence of adenocarcinoma, carcinoma complicating pregnancy, bone metastases, generalized metastases, and cancer primary in a second organ is given for this series.

TABLE 1—SURVIVAL RATE BY YEARS 1 TO 10 FROM 1926 TO 1933—309 CASES

Stage	(Schultz) per cent	No. cases	5 Y survival per cent	10 Y survival per cent
I	4.8	5	71	7
II	3.7	95	51	20
III	35.6	1	16	3
IV	27.0	86		
Composite	100	309	50	59
Relative		5	100	100

TABLE 2—FIVE YEAR SURVIVALS—127 CASES FROM 1936 TO 1938 LAST 3 YEARS

Stage	(Schultz) per cent	No. cases	Yr.	Y	5 Y	4 Y	3 Y	5 Y per cent
I	2.3	5	3	3	3	3	3	100.0
II	30	38	34	20	27	27	26	69
III	48	61	47	30		5	5	64.3
IV	19.7	5	8	3	3	3	3	4
Abscises	100	137	87	63	54	3	30	59.3
Not treated	14.3	18						
Relative	89.7	109					40	44.9

13 cases—needles not used as primary method. One treated elsewhere survived 3 years.

The good results previously reported from the use of interstitial long platinum needles of low intensity are maintained in this series and with the added use of x ray therapy in the last consecutive 109 treated cases, are definitely improved.

Through a more carefully worked out distribution and spacing of the radium sources as suggested by a study of dosage and five-year survival rates it is hoped that these results may be further improved.

ADNEXAL AND PERIUTERINE CONDITIONS

Ziegler, E. E.: Bilateral Ovarian Carcinoma in a Female 30 Weeks Old. *Arch. Path. Chlc.* 1945 40 270.

This is a case report of a carcinoma which apparently was a dysgerminoma arising from granulosa cells in a fetus weighing 1,340 gm. and estimated to be thirty weeks old.

At the routine autopsy the ovaries were slightly enlarged and grayish pink in color. They aroused no special interest during the autopsy and the tissues were removed and sectioned routinely. Histological examination, however, showed that the entire substance of each gland was practically replaced by carcinomatous tissue. The cancer cells contained numerous mitotic figures. Scattered through the neoplasm were numerous primitive granular follicles. In some places the granulosa cells seemed to show stages of transition into neoplastic cells. This gave the impression that the tumor was a granulosa cell carcinoma. The tumor cells themselves, however, resembled those of dysgerminoma, and there was a delicate tumor stroma between the masses of tumor cells which also resembled the stroma of the well known dysgerminoma. There were no gross or microscopic evidences of extension or metastases.

The mother of this infant is living and well and has since given birth to a full term well developed, normal appearing infant.

The occurrence of neoplasia in childhood in infancy and now in fetal life seems to lend weight to the opinion of those who believe in the importance of hereditary as opposed to environmental factors in the causation of cancer. It seems to indicate that at least some cancers may occur without the operation of extrinsic environmental factors.

Grellet, H. E.: The Use of Prostigmine in the Treatment of Amenorrhoea and as a Pregnancy Test (De l'emploi de la prostigmine dans le traitement de l'amenorrhée et comme test de grossesse). *Rev. f. gyn. obst.* 1945 40 250.

Emmenagogues such as apol ergot, and yohimbine were formerly used to start menstruation because they produced congestion in the pelvic organs. They have been replaced by sexual hormones but recent studies again focus attention on

the rôle of hyperemia in the mechanism of menstruation. It has been shown that hormones produce histological transformation of the uterine mucosa which the older drugs were not able to cause, but the ability to create hyperemia and uterine bleeding is common to both groups of drugs. Estrogenic hormones have a double effect: (1) a specific action and (2) a nonspecific action related to the phenomenon of hyperemia. Both male and female sexual hormones display a vasomotor effect, attributable to the ability to liberate a certain amount of acetylcholine which acts on the blood vessels through the parasympathetic system. Acetylcholine is produced *in situ* and not in remote places. Such effect is of short duration, not exceeding 12 hours, because a hydrolytic disintegration of the acetylcholine occurs under the influence of the enzyme cholinesterase present all along the nerve fibers.

Many authors consider that the menstruation results from a vasodilating reflex comparable with erection. Retardation of the menstruation without apparent cause may be attributed to a nervous factor responsible for an insufficiency of the vascular response with a glandular system intact. To remedy such conditions prostigmine has been suggested instead of acetylcholine because it acts on the parasympathetic system by inhibition of the cholinesterase without the dangers associated with acetylcholine. In this manner a rapid disintegration of acetylcholine in the tissues is inhibited and thus a uterine hyperemia is facilitated.

The author employed prostigmine in 86 patients and could check the results in 75. A menstrual delay

of from 5 days to several weeks was recorded in the histories. The material consisted of 30 cases of pregnancy, 10 nonpregnant cases in which endocrine or organic disorders could be excluded and the amenorrhea had to be considered as accidental, and the remainder in which the patients had probable or manifest endocrine disorders.

The author concludes from his investigation that three consecutive injections of prostigmine in women who usually have a normal menstruation are followed by bleeding, usually typical menstrual bleeding. In women in whom an organic or endocrine disorder is suspected such prompt result is considerably less frequent and usually appears only if the injections coincide with the luteal phase. No uterine bleeding occurs if amenorrhea is due to pregnancy. Therefore prostigmine injections may be used as an early diagnostic pregnancy test. If no bleeding follows 3 injections of prostigmine in patients without any evidence of endocrine or organic disorders, the possibility of pregnancy should be considered.

The patient should be informed that the injections will not provoke an abortion.

In 14 nonpregnant patients treated with prostigmine a bloody show appeared within 6 days after the last injection. In patients with amenorrhea postpartum the time which elapsed between the injections and the bleeding was long enough to create doubt as to the efficiency of prostigmine.

The author expresses doubt as to the efficiency of prostigmine in amenorrhea caused by endocrine disturbances.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Bernstine, J. B.: Vaccination during Pregnancy as a Prophylaxis against Puerperal Infections
Med Clin N America 1945 29 1405

The investigator undertook to culture the type of organisms commonly found in puerperal infection test their effect on laboratory animals and by means of a vaccine made from the cultures, elevate the immunity of the pregnant woman to such infections.

Cultures were taken from the cervix and endocervix of pregnant women with a sterile cotton swab placed in a tube of blood agar and subcultured within 30 minutes. The culture media consisted of 5 per cent defibrinated horse blood agar plates, beef infusion broth, pH 7.6 and plain 2.5 per cent infusion agar plates and slants. The common organisms found were the staphylococcus albus streptococcus viridans the diphtheroids nonhemolytic streptococcus and bacillus subtilis.

After a vaccine was prepared as explained in detail in the original article 3 groups of mice were inoculated with various strengths of the vaccine. Following the study on mice, 10 female patients in the childbearing period were selected. No reactions occurred in this group therefore 475 patients attending the maternity clinic at Jefferson Medical College Hospital Philadelphia, were inoculated. There was no particular selection of the patients and later at the time of delivery it was not revealed which patients had been inoculated.

The initial injection was 1 minim with subsequent injections of 4, 8, 12 and 16 minims. The number of injections varied from 8 to 30. The majority of patients received their injections from the fourth to ninth month. There was a noted absence of reactions in these women.

In this series of vaccinated patients, 4.2 per cent were morbid during the puerperium as compared with the nonvaccinated group whose morbidity was 17.1 per cent. This study concluded a series of 973 patients who were vaccinated 503 having been reported upon in preceding papers.

CATHERINE B. HIRS M.D.

Duran, A.: Axial Torsion of the Myomatous and Pregnant Uterus (Torsion axial del utero mioma toso y gravido) *Bol Soc chilena obst gin* 1945 10 119.

Axial torsion of the myomatous and pregnant uterus is very rare. The author has found only 2 cases in the literature before he encountered the one reported in this article. This case was in a woman of 35 years who was found to have a nodular myoma of the uterus complicated by a pregnancy of 12½ months. The myoma was removed the denuded surface covered with bladder peritoneum and the wound sutured. The woman made a complete re-

covery and the pregnancy continued without interruption. The other 2 cases are reviewed briefly.

The name axial torsion is not really correct as this would indicate a torsion of the whole organ around its axis while as a matter of fact there is a rotation only of the body of the uterus around the supravaginal part of the cervix which is lengthened and softened by the existing conditions. The rotation may be to the right or left and may be as much as 180 degrees, so that the anterior surface of the uterus looks backward. Torsion of a nonpregnant myomatous uterus may be as much as 360 degrees. Factors in the torsion are the weight volume and site of implantation of the tumor and the softening and elongation of the isthmic portion of the uterus brought about by the pregnancy. The torsion causes a sudden intense pain irradiating over the whole abdomen, accompanied by syncope a small rapid pulse vomiting cold sweat, and dyspnea. The temperature is normal and there is dissociation between the pulse and temperature. Abdominal palpation reveals muscle rigidity and intense sensitiveness. In cases in which the torsion takes place gradually the symptoms are slight.

Operation should be performed as soon as the diagnosis is made. Detorsion is generally not difficult the uterus may be fixed in position by Passeron's hysteropexy or Pentalosa's pelvic hysterectomy the myoma removed and the denuded zones covered with peritoneum. If the torsion has caused serious circulatory disturbances such as extensive extravasations of blood infarcts or zones of gangrene the uterus must be removed. If no great circulatory changes have taken place and the myomectomy has left the wall of the uterus in good condition the pregnancy may continue. However if the site of implantation of the myoma is very large or serious nutritive disturbances of the wall of the uterus have taken place the uterus may rupture.

AUDREY G. MORGAN M.D.

PUERPERIUM AND ITS COMPLICATIONS

Rosenblum, G. Melnikoff, E. and Fiat, H. S.: Early Rising in the Puerperium *J Am M Ass* 1945 129 849

The practice of early rising of parturient women dates back to ancient times. Although it was recently stimulated by the wartime shortage of obstetric beds it did not arise from that emergency. The puerperium or time of rest given to women in childbirth has varied more widely in the customs of different peoples than any other feature of that great physiological function of woman.

The practice of early ambulation of surgical patients now a widely accepted procedure and advocated by hundreds of articles in the American and foreign literature must be considered intimately

related to the practice of early puerperal rising. The objectives and underlying principles of the two are identical.

With a background of favorable evidence in the literature the task of studying early ambulation in the puerperium was begun. At the outset it was realized that there would be objections both from patients and from the medical profession to the practice of early ambulation. The following objections arose during the course of their study.

The objections of doctors were (1) fear of medical-legal consequences, (2) fear that episiotomies would break down (3) fear that there might be too much strain on the pelvic floor resulting in prolapses and retroversions, (4) fear of excessive postpartum bleeding and (5) fear that patients would not approve of early rising.

The objections of the patients were (1) that the procedure was unfamiliar to them, therefore they were not sure it was good (2) that they needed rest and it might tire them too much to get up (3) that they were too weak to walk, (4) that arising might make them bleed too much and (5) that they might break their stitches.

A group of 532 obstetric patients who were studied were divided into three groups as follows (1) 247 early risers ambulatory on the first or second postpartum day (2) 106 intermediate risers, ambulatory on the third or fourth postpartum day and (3) 229 late risers ambulatory later than the fourth postpartum day.

The study of bladder function showed a close similarity of the catheterization curves for the three groups. The contention that early puerperal rising may cause excessive bleeding is disproved by the statistics, which show actually less frequent abnormal bleeding in the early group than in the late group. Involution of the uterus was uniformly good in all groups. The fear that early rising would cause a breakdown of episiotomy or abdominal wound incisions is likewise unfounded, only 1 instance of perineal skin separation occurring in the entire series, and this in a patient in the late rising group. More efficient mobilization of the bowels was evident as more than three times as many spontaneous bowel movements occurred in the early as in the late group.

The total number of complications in the entire series was very small, and there was no significant difference among the three groups. As there were no patients having emboli or thromboses in the entire series, the contention of many previous authors that late rising fosters these complications was not proved in this series. However a study of a much larger series might possibly reveal a lower incidence of these complications in the early risers.

The claim advanced by some obstetricians that early rising may cause later prolapse and retroversions is also disproved. Of the early risers examined at 1 month and at 6 weeks 28.7 per cent had either a midposition or retroversion of the uterus, while

34.6 per cent of the intermediate and 24.4 per cent of the later risers had the same positions—relatively similar totals. This indicated that early rising causes no significant alteration in the position of the uterus, at least within a period of from 4 to 6 weeks following delivery. Prolapse did not occur in any patient in the entire series.

The nurses working in the obstetric department reported a decided reduction in the amount of nursing care required for patients rising early. They noted better morale and less discomfort in this group.

Particularly favorable are the reports concerning cesarean sections in which cases less abdominal distention and discomfort, and a much more rapid convalescence was noted.

No patient in either the early or the intermediate group offered any criticism concerning the early rising. In fact, the majority exhibited enthusiasm. The multiparas especially were impressed, stating that they felt better and stronger than they had after previous confinements, when they had spent a period of from 7 to 14 days in bed.

CHARLES BARTON, M.D.

MISCELLANEOUS

Van Wageningen, G.: The Optimal Mating Time for Pregnancy in the Monkey. *Endocrinology* 1943, 37: 397.

Since the rhesus monkey (*macaca mulatta*) is the laboratory animal of choice for the study of the physiology in reproduction, any knowledge concerning the optimal mating time for pregnancy is of considerable interest.

The author reports on a series of observations extended over a 5 year period on monkey breeding. During this study a rigorously standardized plan for mating at a particular time in the menstrual cycle was used.

The routine procedure was to place the female on the eleventh day of her menstrual cycle in the cage of a male for a period of forty-eight hours. Thirty-two per cent of such matings resulted in pregnancy. Another forty-eight hour mating starting on the thirteenth day of the menstrual cycle resulted in pregnancies in 24 per cent of the cases.

Another series of 35 monkeys were studied and their mating date was delayed to the seventeenth day of the menstrual cycle. These animals were mated more than an average of three times each, eighty times in all, but at the end of 4 months only 1 pregnancy had been effected. In contrast, when the remaining 24 monkeys then were mated on the eleventh day of their next cycle 7 of them became pregnant.

The author concludes that in this particular monkey the period between the eleventh and thirteenth days of the menstrual cycle is the preferred time for mating.

HARRY FIELDS, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Huggins, C. B., and Scott W. W.: Bilateral Adrenalectomy in Prostatic Cancer. *Ann Surg* 1945 122 1031

Abundant use of plasma transfusions seems to be of great importance in the prevention of circulatory collapse following adrenalectomy in man.

The author states that inadequate therapy after adrenalectomy in man results in early hyperpyrexia and hypotension, the carbohydrate metabolism is not drastically disturbed. In the adrenalectomized man adequately treated with plasma, adrenal cortical extract, and desoxycorticosterone acetate these effects were not observed, but Addisonian pigmentation occurred on the sixteenth postoperative day and was progressive.

Complete adrenalectomy in castrate man results in a reduction of 17 ketosteroids to values less than 3 mgm. excreted in the urine daily, total ketonic, and α fractions are greatly diminished. Urinary androgens as measured by the comb-growth technique are absent. There is a continued excretion of small amounts of estrogen. In a man who survived complete adrenalectomy for 116 days there was a sustained reduction of alkaline phosphatase activity of the serum but the prostatic cancer progressed although apparently at a retarded rate. The injection of desoxycorticosterone acetate elevated the blood pressure to normal levels but hypertension did not occur with massive doses.

The extragonadal androgenic depot in man is the adrenal.

Adrenalectomy is not a practical method of treatment of the failure-group of patients with prostatic cancer treated by antiandrogenic methods.

Three factors, whose presence and significance vary in the human prostatic cancers may be stated: (1) the testicular androgens (2) the extragonadal depot and (3) androgen-dependence or its opposite androgen independence. It is not yet possible to define androgen-dependence or independence in chemical terms.

JOHN A. LOYER, M.D.

Horta, J. S.: The Question of Origin of Grawitz Tumors (El problema del origen de los tumores de Grawitz). *Arch. Espan. Urol* 1945 2 115

There is no unanimity of opinions as to the origin of Grawitz tumors but at present there is more and more tendency to accept the renal theory. Modern biological studies of the functions of tumors originating in endocrine glands justify a revision of the older theories pertaining to the origin of Grawitz tumors.

A priori we may consider Grawitz tumors as originating from a normal structure of the adult kidney. Apparently such neoplasms do not derive from intrarenal inclusions of the suprarenal glands. There are arguments based on morphologic and bio-

logical considerations which tend to show that hypernephroma does not originate from aberrant suprarenal glands within the kidney.

Undoubtedly there is a great microscopic similarity between such tumors and the suprarenal cortex. In many cases it is impossible to distinguish microscopically a hypernephroma from the suprarenal cortex in both, the fat and glycogen are present in very small amounts or they are absent entirely. Cellular protoplasm is scanty and fusiform formations are present. Ewing maintains that nododifferentiated cells frequently found in a suprarenal carcinoma, are not present in the renal glands.

Sarcomatous structures may be present in Grawitz tumors as well as in the suprarenal cortex. The author shares Ewing's opinion as well as that of Apitz who maintains that both Grawitz tumors and those of the suprarenal cortex may have a sarcomatous structure which derives from epithelial cells, the renal epithelium and that of the suprarenal glands are of mesothelial origin.

Frequency of papillae and lucid spaces is characteristic for parenchymatous tumors of the kidney while in corticosuprarenalomas they are very rare. Such formations in suprarenal cortex tumors are of glandular origin. Under low power both kinds of tumors may look identical but under high power cells of renal tumors show a typical vegetative aspect only the exoplasm is stained while the remaining cytoplasm remains colorless. Large fat droplets may be seen in sections of Grawitz tumors stained with Sudan III while the droplets are very small in corticosuprarenalomas. The vegetative aspect of cells in renal tumors is caused by the accumulation of glycogen. That cellular formations are practically reduced to cytoplasm in corticosuprarenal tumors cannot be denied but according to the author's opinion such images are secondary.

The fact that hypernephromas do not produce alterations of the sex characteristics of the host is interpreted by some writers as an argument against the suprarenal theory. Not all tumors of the suprarenal cortex are accompanied by such modifications. From the hormonal point of view the cortical tumors may be divided into (1) those which do not produce hormonal changes (2) those which are accompanied by an excess formation of estrogens, (3) those with a symptomatology related to the excessive production of metabolic steroids and (4) those accompanied by an increased excretion of androgens and steroids. To the author's knowledge not a single case of renal hypernephroma with virilism has been reported in the literature.

The presence of numerous vacuoles in suprarenal tumors but not in hypernephromas is stressed.

Contrary to the rarity of aberrant suprarenal nodules of the kidney aberrant Grawitz tumors are relatively frequent.

The author believes that there are sufficient arguments in favor of the theory which claims that Grawitz tumors do not originate from suprarenal tissues.

Renal hypernephroma belongs to the group of neoplasms of the endocrine glands characterized by the presence of lucid cells such as benign cortico-suprarenal tumors, leucomas or hypernephromas of the ovaries, tumors of the interstitial gland of the testes, and parathyroids.

Hypernephromas of the kidney are sometimes accompanied by hypertension but it has been pointed out that no definite relations exist between these two conditions. Hypertension may persist after nephrectomy has been performed on account of the presence of a Grawitz tumor.

Hypernephromas possibly originate from myo-epithelial formations described by Goormaghtigh, who considers them as regulators of the circulation within the glomeruli. JOSEPH K. NARAT M.D.

Santaella, R. A.: Voluminous Pyonephrosis and Its Treatment (Las pñeufrosis vol minosa y su tratamiento) *Arch. esp. med.* 1945: 2.

The author advocates a nephrectomy in two stages in the treatment of extensive pyonephrosis. His clinical observations and anatomopathological studies demonstrated the advisability of such staged procedure. Perifocal sclerotic reaction safeguards against a spreading infection by establishing a defensive blockade. Usually 1 month is allowed to elapse between the first stage which consists of nephrostomy and insertion of a Pezzar catheter and the second stage the nephrectomy proper. The operation is performed only if the functional capacity of the kidney is good. The hilus is ligated en masse. Frequently the author leaves a clamp on the pedicle for 3 weeks.

Six cases in which two stage operations were performed are described in detail.

JOSEPH K. NARAT M.D.

Castro, E. P.: Renal Tuberculosis (Tuberculosis renal) *Arch. esp. med.* 1945: 59.

The author reports a case of renal tuberculosis in a 34 year old man who had repeated attacks of pain in the hypogastrium, combined with a great frequency of urination. The pains would disappear after the application of heat. The last attack was complicated by an intensive hematuria with blood clots, chills and fever. All the symptoms disappeared after the administration of pyridium. Three months later the patient was admitted to the hospital. X-ray studies disclosed a dense homogeneous, well circumscribed shadow extending from the right hilum region to the diaphragm. There was a clear space in the center of the shadow. Hematological and bacteriological studies established the diagnosis of pulmonary abscess. The patient was treated with short waves.

The expectoration and fever subsided and the second roentgenogram showed evidence of cicatrization of the pulmonary abscess and the existence of

bronchiectasis in the right lower lobe. The patient complained of vague pains in the left renal region and the epigastrium. The urine contained a large amount of pus. Chromocystoscopic examination showed a normal function of the right kidney while after the injection of indigocarmine only very pale fluid was escaping from the left ureter. Retrograde pyelography showed a large cavity above the upper calyx, with irregular outlines after intravenous urography an image of the cavity in the left kidney was obtained.

A nephrectomy was performed with great difficulty on account of adhesions around the upper pole of the kidney. The patient made an uneventful recovery.

The histological examination revealed a tuberculosis of the kidney with numerous Langhans' giant cells, epithelial cells and lymphocytes. There was an intensive sclerotic reaction. The glomeruli had undergone a hyaline degeneration. Extensive necrotic zones were spread throughout the entire renal tissue in the involved region.

The symptomatology and the roentgenographic studies pointed to a renal neoplasm. The inspection of the extirpated kidney also suggested a tumor rather than renal tuberculosis.

A check-up 3 years later showed the patient to be in perfect health. JOSEPH K. NARAT M.D.

Gorro, A. P.: Partial Nephrectomy (Nefrectomia parcial) *Arch. esp. med.* 1945: 29.

A partial nephrectomy is indicated when a circumscribed area of the kidney is involved the remaining parenchyma appears normal, and the excretory pyeloureteral portion is not affected. An extensive mutilation of the organ in such cases is not justified.

Partial nephrectomy advocated by a number of older writers, was later discredited on account of operative or postoperative hemorrhages, and the formation of obstinate urinary fistulas which required an ultimate extirpation of the organ. For these reasons, improper indications such as the presence of a malignant neoplasm or of tuberculosis of the kidney also discredited the operation.

Recent advances in urological diagnosis, such as urographic studies, and improvement of the technique rehabilitated the operation.

Experiments on animals show that a portion of the renal parenchyma corresponding to one-fourth of the entire amount of both kidneys is sufficient for the survival of the animal. An extirpation of a portion of the kidney does not unfavorably alter but rather improves, the function of the remaining part of the kidney.

A decision to resect only one part of the kidney cannot frequently be made until the surgeon is able to inspect the organ. Conditions of the blood supply and permeability of the pyeloureteral system are the most important factors to be considered. Aortic arteriography before the operation may furnish valuable information as to the blood supply to the

kidney. Pyelography furnishes information as to the condition of the excretory pyeloureteral apparatus.

Partial nephrectomy is indicated in a partial hydronephrosis located at one of the poles of the kidney. If lesions caused by a stone are extensive, a simple extraction of the calculus does not assure anatomic restitution of the involved parenchyma and in such cases a partial nephrectomy furnishes excellent results because it prevents an extension of the inflammatory process. A partial nephrectomy is indicated if a large solitary cyst is present.

If a hydatidiform cyst does not communicate with the excretory ducts, a partial resection of the kidney may be considered. If in a polycystic kidney the changes are confined chiefly to one portion of the organ, the affected area may be removed and the cysts disseminated over the surface of the kidney may be destroyed with the cautery.

Sometimes abnormal blood vessels interfere with pyeloureteral evacuation and in such cases a section of the abnormal blood vessels which may lead to an ischemia of the corresponding part of the kidney may be avoided by a prophylactic partial nephrectomy. Otherwise a septic necrobiosis may result.

If a destructive renal infection is confined to one portion of the organ, the affected area may be resected and a drain inserted.

Only on rare occasions is a partial nephrectomy indicated in renal tuberculosis. This may be the case if the infection affects a kidney with a double pyeloureteral system which permits a functional and roentgenographic study of both portions of the kidney. Such studies may reveal an integrity of one part of the kidney.

Anomalies of the renal pelvis with or without infection may show that two parts of the kidney function independently of one another. In such cases a plastic pyeloureteral operation, when there is a congenital anomaly may supplement a partial resection of the kidney. Such an operation may be considered if a benign neoplasm involves only one part of the kidney.

In many cases of injury of the kidney a partial resection of the organ is justified.

One of the drawbacks of a partial resection is the hemorrhage; this can easily be stopped with the electrocautery. The second drawback is the difficulty encountered in the determination of the extent of the lesion. Roentgenographic studies are extremely valuable in this respect.

A few essential points in the technique must be kept in mind. The blood vessels supplying the portion to be resected should be ligated prior to the resection, especially if one is dealing with an abnormal kidney. Many authors described a technique of approximation of the wound edges. However in many instances the wound in the kidney cannot be closed without an insertion of a flap consisting of muscle tissue and aponeurosis. Such portions of the tissues may be obtained from the external oblique muscle. Difficulties in approximating the edges are encountered when a transverse or a wedge shaped

incision is made in the kidney. The inserted musculoaponeurotic strip is kept in place with interrupted catgut sutures. The author uses interrupted catgut sutures for approximation of the edges which transfix the parenchyma and the fibrous capsule.

Efficient extrarenal drainage for from 8 to 12 days provides evacuation of the extravasated urine. Otherwise an infiltration of the soft tissues with abscess formation may result.

The author performed a partial nephrectomy on 16 patients. He encountered the following anatomic abnormalities: a superior polar artery, both superior and inferior polar arteries, double renal pelvis, and a normal kidney with a double pelvis and ureter. The following pathological conditions were found: pyelonephritic infection, hypoplasia with a complete double ureter, tuberculosis of a kidney with a double pelvis and ureter, congenital uretero-hydronephrosis with a double pelvis and ureter, infected hydronephrosis with a double pelvis, calculous pyonephrosis with a double pelvis, lithiasis with infection, tumor of the kidney, hydronephrosis, inferior polar artery, circumscribed dilatation of a calyx, and traumatic rupture of the kidney.

In 5 cases transparenchymal drainage of the renal pelvis was employed. In 4 cases the urine was escaping from the lumbar incision for a few days following the operation. In 2 patients the urinary discharge stopped spontaneously between the fifth and tenth postoperative days while in the remaining 3 cases the discharge lasted from 3 to 4 weeks. In 1 patient a urinary fistula opened and closed repeatedly for a few months until a small stone was expelled spontaneously. In 1 patient symptoms of an acute pyelonephritic infection developed. The condition was attributed to a premature removal of the intrarenal drain on the tenth postoperative day. Following the introduction of a ureteral retention catheter the infection subsided in 30 days.

JOSEPH K. NARAY, M.D.

Frostad H.: Urinary Stasis and Pains after Cystoscopy with Catheterization of the Ureters. *Acta chir scand* 1945 93 546

Frostad studied 95 cases in which preliminary intravenous pyelography excluded urinary tract calculi and in which pain or colic followed retrograde pyelography. After ureteral catheterization patients frequently complain of pain, and the urine from one or both ureters is bloody. Postcystoscopic intravenous pyelography demonstrated a characteristic urinary stain on the affected side. In 3 cases removal of a blood clot projecting from a ureteral orifice resulted in immediate cessation of the pain. In the series cases with reduced renal function were excluded.

Postureteral catheterization pain usually starts in one or both lumbar regions and in 2 to 3 hours gradually spreads downward along the course of the ureter to the inguinal regions. The pains may vary in intensity corresponding to ureteral peristalsis. They seldom begin quite suddenly as in calculous

colic, but begin and decrease gradually. They usually begin a few hours after completion of the cystoscopy. Of the 95 patients, 33 had postcatheterization pain. Pain usually occurred when blood was most excessive during collection of the ureteral catheter specimens. A fairly constant relationship between the intensity of the pain and the amount of bleeding during collection of the specimens was present.

Of the 33 patients with postcatheterization pain, 28 had intravenous pyelography immediately after commencement of the pain. In all cases more or less complete stasis on the affected side was found and the duration of the stasis varied from 1 to 6 hours. When the pains disappeared, the stasis disappeared at once. Among 19 cases without pain, intravenous pyelography did not demonstrate stasis in any instance. Other causes of stasis, such as cal-

culi ureteral rupture, gravidity adjacent tumors or abscesses, and allergic reactions would have been ruled out by the preliminary intravenous urography. The most probable cause of stasis is the formation of blood clots which for a time obstruct the ureter after ureteral catheterization.

DAVID ROSENBLUM, M.D.

Prince, C. L.: Lumbar Ureterolithotomy; The Foley Operation. *J. Urol.*, Balt., 1945 54 368.

The intention of Prince is to bring to the attention of the surgical profession the simple operation of lumbar ureterolithotomy which was introduced in 1935 by F. E. B. Foley. The author believes that this simple procedure with no cutting of muscles, without freeing of the ureter with ease of exposure, and with rapid convalescence has been neglected by the profession.

Fig. 1.

Details of the operative technique including excellent illustrations by Didusch are given (Figs. 1 and 2). Briefly exposure of the ureter in its upper third consists of making a short (7 or 8 cm.) incision parallel to the twelfth rib with the midpoint of the incision at the end of the twelfth rib and at a distance below the rib equal to the distance of the ureteral stone below the twelfth rib as determined with x rays. Dissection is carried downward to the lumbodorsal fascia by bluntly separating the latissimus dorsi posteriorly and the external and internal oblique anteriorly, and stripping these muscles from the lumbodorsal fascia below. The lumbodorsal fascia is then opened in the direction of its fibers and the fascia of Gerota stripped from its under surface. The posterior layer of Gerota's fascia is separated bluntly from the quadratus lumborum and psoas

muscles down to the vertebral bodies. At this point the ureter can be seen and opened the stone removed exploration made with bougies closure is easily accomplished. It consists of suture of the muscularis and perireteral tissues with interrupted fine catgut and then suture of the lumbodorsal fascia subcutaneous tissue and skin. A Penrose drain is placed for 2 or 3 days. The muscles do not require suturing.

Convalescence in these cases has been smooth. There has been no shock or mortality. The average hospital stay following the Foley operation in 14 cases reported by the author was 7 days. During the usual muscle splitting and cutting procedure for stones in the upper third of the ureter the average hospital stay in 14 comparable cases was 28.4 days.

BLADDER, URETHRA, AND PENIS

Ballesteros, M.: Cystometry (La cistometría) *Rev med* 1943 3 206

After a brief historical review of cystometry and a short description of the anatomic, pathological, and physiological conditions of the bladder the author describes various models of apparatus used for cystometric measurements and the technique of cystometry.

Cystometry is of great importance for the discovery of disturbances of the bladder function of neurogenic type or those caused by a reflex from adjoining organs. The method is particularly valuable in cases in which locomotor ataxia is combined with hypertrophy of the prostatic gland.

The average figures obtained by the author differ somewhat from those published by North American workers. According to the author's investigation the pressure curve indicated a normal capacity of the bladder of from 150 to 300 c.c. The maximal voluntary pressure in normal individuals ranges from 38 to 62 mm. of mercury. In hypertonic individuals the capacity of the bladder is below 150 c.c. and the maximal voluntary pressure exceeds 62 mm. of mercury while in hypotonic individuals the bladder capacity exceeds 300 c.c. and the maximal voluntary pressure remains below 32 mm. of mercury. In normal individuals the curve ascends gradually while in hypertonic individuals it rises rapidly and in hypotonic patients it is low. The maximal physiological capacity of the bladder ranges from 200 to 700 c.c. Among cystometrographs, the one devised by Lloyd G. Lewis is the most precise instrument the electrocystometrograph of Landes and Vorn is also a dependable apparatus.

Sphincterometric measurements are also of great importance as they supplement cystometric studies.

The most complete cystometric apparatus is the so-called microcystometer devised by Irving Simons.

The author discusses various sources of error such as infection of the bladder, excessive rapidity of the injection of the fluid, rectocele, cystocele and diverticula of the bladder which may produce a hypotony of the detrusor muscle, stones in the bladder and tumors or infectious processes which may produce hypertonia. Leifer W., Martin S. P., and Kirby W. M. M.: The Treatment of Gonococcal Urethritis with Single Injections of Penicillin Beeswax Peanut Oil Mixtures. *J. Engl. med. J.* 1945 233 583

The procedure and materials used for the treatment of gonococcal urethritis were essentially the same as those described by Romansky and Rittman in 1914 (*Science* 100 106). The viscous preparation—even when heated in an incubator or in a water bath at 37 C for 30 minutes—was withdrawn into a syringe by a 15 gauge needle and then injected into the buttock through a 30-gauge needle. The site of injection was not massaged. No local or systemic

manifestations of toxicity of any significance were noted. In most cases pain and tenderness were present at the site of injection for from 24 to 48 hours, but these were no more severe than when penicillin in saline solution is used.

In every patient treated in this series clinical improvement was noted initially. Dysuria subsided during the first six or eight hours and the purulent discharge became mucoid and watery. By the end of the second day almost every patient was free of symptoms and the urethral discharge had ceased.

One hundred and ninety-two patients of the total of 217 whom the authors treated by this method could be followed up for 31 days and only these were considered in evaluating the results. In 24 of these treatment resulted in failure however there was a clinical recurrence with the return of urethral discharge, from which gonococci were cultured in only 10. In the other 14 the gonococcus was detected by bacteriological methods alone. All of the 24 patients in whom treatment was considered a failure were eventually cured by further penicillin-beeswax peanut oil therapy or by treatment with divided doses of penicillin in saline solution.

In reviewing these results, no noteworthy effects due to the character of the excipient used, e.g. the percentage of beeswax used, or the salt of penicillin employed (calcium or sodium) were noted, nor did the race of the patient (negro or white) make any difference, although the white patients were found to be slightly more refractory. Of the total 192 in the series who were followed up for 31 days, 83 were treated with 100,000 units of penicillin, and of these 74 (84%) were cured; 97 were treated with 300,000 units and of these 83 (91%) were cured. The remaining 13 patients were given 300,000 units and of these 11 were cured however the last group was too small to be significant.

From these results the authors conclude that a single intramuscular injection of 100 c.c. of a mixture containing 300,000 units of penicillin in 4 to 6 per cent beeswax by volume in peanut oil appears to be a highly satisfactory method of treating acute gonococcal urethritis. JOHN W. BRIDGMAN, M.D.

Gastro E. P.: Epithelioma of the Urethra; Nodular Form (Epithelioma de uretra form nodular). *Arch. esp. med.* 1945 140.

The author collected 18 cases of epithelioma of the urethra from the literature and reports a case of his own in a man, aged 48 years, who had noticed an enlargement of the glands 8 months prior to the admission to the hospital. Simultaneously a hemorrhagic secretion began dripping from the meatus. Gradually burning pains developed and were responsible for impotence because they were interfering with erection.

There was a very marked phimosis. Palpation showed the glands to be transformed into a globular hard mass, painful to the touch. The local temperature was increased. A sanguinous secretion was escaping from the urethra. A catheter could not

be introduced because it was encountering a mass just behind the meatus. The testes and epididymes were normal and no enlarged inguinal glands could be palpated. The Wassermann reaction was negative.

A biopsy was performed and the examination of the piece removed from the endourethral mass established the diagnosis of a spinocellular epithelioma.

An operation was performed under low spinal anesthesia. The involved portion of the penis was removed. An inspection of the specimen showed the entire navicular fossa to be occupied by a cauliflowerlike neoplasm.

Histological examination showed a malignant neoplasm consisting of the squamous type of epithelial cells which were penetrating the skin and forming numerous ramifications and anastomoses. The stroma was relatively scant. A hyaline degeneration of the epithelium was noticed in many places and there was evidence of a chronic inflammatory reaction in the stroma in the form of an infiltration with plasma cells, lymphocytes, and a few polynuclear cells. Mitoses were relatively few.

Urethral epithelioma usually causes severe pain which interferes with micturition and sexual power. The frequency of urination may be increased or a complete retention may develop. The latter may disappear when necrosis of the tumor re-establishes free passage. As a rule symptoms of penurethritis accompany the induration. In doubtful cases a urethroscopic examination may be required. Biopsy allows the differentiation of an epithelioma from adenomatofibroma, fibroma, or fibromyoma while serological examinations exclude syphilitic lesions. Inguinal adenopathies are relatively frequent.

Chronic inflammatory strictures, fistulas, and leucoplakia are considered as predisposing factors. In 60 per cent of the cases the tumor has been found in the perineal portion of the urethra.

The tumor may be either nodular or infiltrating. Both types show a considerable peripheral growth. Necrosis of the tumor tissue may lead to the formation of perurethral abscesses.

Metastases are found in the inguinal epigastric and mesenteric regions.

Cylindrical cell formations or adenocarcinomas deriving from Littre's glands are rare and in the majority of cases a squamous-cell tumor is found. This is due to the frequent metaplasia of cylindrical urethral epithelium.

The therapeutic method of choice is an amputation of the penis if the epithelioma is located in the anterior urethra. Involved inguinal glands should be removed. A removal of the testes is superfluous because they have an entirely independent lymphatic circulation.

The prognosis is much worse if the epithelioma involves the posterior urethra, while chances of cure are reasonably good if the tumor is confined to the anterior portion.

An early diagnosis is essential

GENITAL ORGANS

Boyd, H. L. The Use of Thrombin (Topical) in the Control of Bleeding Associated with Prostatic Surgery. *J. Urol. Balt.* 1945 54 385

Boyd suggests the topical use of thrombin for the control of bleeding during and following perineal prostatectomy in the cases in which bleeding cannot be controlled by ligation of the bleeding points and the supplementary use of the Davis bag and gauze packing. In his introductory remarks Boyd reviews the previous successful use of thrombin by O. Conner in cases of excessive hemorrhage following transurethral electroresection and suprapubic prostatectomy.

In 12 cases of excessive bleeding following perineal prostatectomy in which control by ordinary means proved impossible thrombin was used. The technique is given in detail and consists briefly of the application of a gauze sponge (3 inches long) soaked in thrombin solution (5,000 units in 20 cc. of normal saline solution) to the bleeding areas within the prostatic capsule, the sponge being brought out of the wound beside the Davis bag.

In 1 case in which the Davis bag became partially deflated and passed into the prostatic bed, profuse bleeding was controlled by clamping the Davis bag introducing the thrombin solution through the urethra, clamping the urethra and permitting no irrigation and no catheter drainage for a period of 4 hours.

In 1 case excessive bleeding was controlled with thrombin introduced and localized to the prostatic space by means of the Trattner partition catheter.

WILLIAM W. SCOTT, M.D.

Millin, T.: Retropubic Prostatectomy: a New Extravesical Technique. *Lancet* Lond. 1945 249 693.

The outstanding features of retropubic prostatectomy are:

1. It is an extravesical procedure by which suprapubic bladder drainage with its risk of slow closing or persistent fistula is avoided.

2. It is applicable to all types of prostatic obstruction.

3. It is relatively short and shock free.

4. It appears to be anatomically sound, no important organs being interfered with or endangered.

5. The mortality is singularly low. No deaths have occurred in the first 20 cases.

6. The postoperative course is easy for the patient and attendant staff.

7. The whole of the obstructing tissue is removed so the risk of recurrent obstruction is obviated.

8. The postoperative stay in the hospital seldom exceeds 2 weeks.

Preoperative treatment. When the signs or symptoms suggest the necessity or desirability of operative intervention the usual preliminary tests of renal and cardiovascular functions are made. Particular emphasis is laid on preliminary intravenous

Fig. 1. Retropubic approach to the prostate: P, pubis, B, bladder, R, retractor

urography. From this study is ascertained evidence of ureteric dilatation, unexpected gross hydronephrosis, vesical diverticulum, urinary calculi, and approximate residual urine without the necessity of urethral instrumentation. When actual retention has supervened suprapubic puncture is being tried initially with a small hydrocele trocar and cannula, and repeated when necessary until renal function studies have been made. When the initial puncture reveals infected urine, a No. 8 rubber Fiemann catheter is passed per urethram and retained *in situ*. When the urine is uninfected and renal function adequate urethral instrumentation is not used before the patient is on the operating table.

Operative technique. The patient having been anesthetized either by low spinal anesthesia, with pentothal, or with pentothal and gas-oxygen, as indicated a rapid cystourethroscopic examination is made to rule out unexpected bladder pathology and to study the exact configuration of the gland. The bladder is emptied, and while the surgeon is changing his gloves and gown, the assistant prepares the operative field, i.e. the lower abdomen and penis. The penis is covered with a loose sterile towel. A midline incision is made starting over the pubis and extending upward $3\frac{1}{2}$ or 4 inches, according to the obesity of the patient. This is deepened in the usual manner and the sponeurosis is incised in the whole length of the wound. Bleeding points are caught in hemostats and coagulated with the diathermy needle. The recti are then separated in the midline and the index finger inserted at the lower extremity sweeps the retropubic fat and peritoneal fold upward. A modified Harris self retaining retractor is then introduced. The lateral blades keep the recti widely separated and the posterior blade presses the bladder upward and backward (Fig. 1).

A flexible lamp resting on the pubis is dipped into the retropubic space thus opened up and the distribution of the veins coursing upward on the anterior and lateral aspects of the prostate is noted, as this appears to vary considerably. The veins are situated in the prevesical layer of the endopelvic fascia. The central leash arising from the deep dorsal vein of the penis is under-run with the boom-

erang needle and ligated. The group on each side is similarly treated. The fat still adherent to the lateral aspects of the gland is gently sponged downward and outward, any veins inadvertently torn in this process being promptly seized with hemostats and subjected to diathermy. The anterior and lateral surfaces of the gland being cleared in this way a medium sized swab is pushed into each lateral recess.

With a diathermy knife or No. 15 Bard Parker knife a curved transverse incision, convex downward, 1 cm distal to the bladder neck, is made through the prevesical fascia and true prostatic capsule. Suction is maintained to keep the field dry and to enable the operator to grasp any bleeding vessels in the distal lip with curved Kocher forceps. With these forceps used as tractors the lower flap is undermined toward the apex of the gland with Devine's long dissecting scissors. The Kocher forceps are removed after being touched with the diathermy needle. The upper flap retracts because of the pull of the severed pubovesical muscles. The anterior and much of the lateral aspects of the false capsule now being exposed an inverted V incision is carried down to the adenoma, which is readily recognized by its typical whitish appearance. The V shaped flap is elevated, which opens up a loose shaped space. With the closed curved dissecting scissors the lower margins of the lateral lobes are freed from the false capsule. The dissection may be continued with the scissors, or, as the author prefers, with the finger. For this purpose it is best to remove the retractor temporarily. The lateral lobes and when present, the middle lobe, are freed digitally from below upward until they present in the wound, being attached solely in the region of the bladder neck. The pedicle is seized on each side with Kocher forceps and the adenomatous mass is detached with scissors or the diathermy needle. The forceps are touched with the diathermy needle and removed. In 1 instance only has a steady finger in the rectum been necessary.

The retractor is now replaced the field swabbed and sucked dry and the edges of the false capsule are secured with 4 pairs of Allis forceps. By traction on these and suitable manipulation of the flexible lamp and sucker the prostatic bed is carefully inspected. The two prostatic arteries, if not already secured in the pedicle, are easily seen bleeding close to the bladder neck at 5 and 7 o'clock. They are seized with hemostats and coagulated. Any other obvious bleeding vessels are similarly treated. This exposure enables one to see large or small adenomas not infrequently left behind during enucleation by any route. They are detached with scissors.

Bleeding having been controlled, the towel covering the penis is then raised and a No. 18 Harris catheter passed along the urethra into the prostatic cavity and thence guided into the bladder. With the assistant steadying the Allis forceps on the margins of the false capsule, the operator closes the defect with a continuous suture of No. 0 catgut, using the boomerang needle. The transverse incision

In the true capsule is then approximated over this with 3 or more interrupted No. 0 catgut sutures. All obvious bleeding should now have been controlled. The lateral recess packs are removed, the field is gently swabbed dry of clot and sprayed with sulfanilamide powder, and a small corrugated drain is placed down to the suture line. The self retaining retractor is removed and the rectus sheath closed with interrupted No. 2 catgut sutures. The skin is closed with silk worm gut. Bilateral vasectomy is then performed. The catheter is next irrigated with 1/5000 flavine to free it from any clot it may have collected during its passage through the prostatic bed. Four ounces of fluid are left in the bladder and the catheter is spigoted. Two silk worm sutures fix the catheter to the skin of the penis. A 4 foot length of sterile tubing with a glass connection of even bore is then attached to the catheter, the lower end of the tubing being spigoted. The operation time need not exceed half an hour and is often nearer 20 minutes.

JOHN A. LOER, M.D.

MISCELLANEOUS

Cordonnier J. J.: Vesicoureteral Reflux Accompanied by Renal Colic. *J Am Med Ass.*, 1945 129 662.

The role of vesicoureteral reflux in the production of renal colic was brought to our attention by Lewis and Carroll in 1934. All cases described by them were secondary to vesical neck or urethral obstruction, and the typical renal colic occurred in the presence of a distended bladder when the patient attempted to void.

Diagnosis is established by filling the bladder with an opaque solution, taking an x ray film, having the patient void, and then taking a second film.

The etiological factors are: (1) mechanical obstruction of the vesical neck with upward dilatation and alterations of the ureteral orifice due to chemical, inflammatory and postoperative changes; (2) patent ureteral orifices associated with nerve lesions as in cauda equina lesions; and (3) congenital urethral valves.

Two cases with typical renal colic caused by vesicoureteral reflux are presented.

Vesicoureteral reflux should be suspected in cases of renal colic, particularly if no stone is demonstrable and vesical neck obstruction is present. Postoperative ureterovesical valve closures may be followed by vesicoureteral reflux. A routine cystogram alone may cause a reflux to be overlooked, and a second film, taken after the patient has voided, should be taken.

DAVID ROSENBLUM, M.D.

Marshall C. J.: Tubercle Bacilluria. *Brit J Urol.*, 1945, 17 103.

While a series of 11 cases is much too small for statistical analyses it may however bring out a few points of particular interest.

The presenting symptoms of these cases of tubercle bacilluria were the classic triad found in urinary

tuberculosis but in addition the importance of the node in the epididymus was fully borne out. Whether every case of chronic epididymitis should be subjected to full urinary investigation remains for discussion. It would seem however that there is one unequivocal indication—the examination of the twenty-four hour specimen for cells and bacilli. This simple but nevertheless searching test should never be omitted. Open tuberculosis cannot fail to make itself evident at least by the presence of leucocytes, if not of bacilli; the presence of either or both, of course, calls for the full roentgenographic investigation with cystoscopy.

There remains the case of closed tuberculosis in which cells are not found in the twenty-four hour specimen. Such cases must be uncommon but nevertheless they are on record. Such cases will be missed unless excretory roentgenography at least is performed.

The overwhelmingly important question however is that of treatment. In view of the evidence that small lesions do heal, even with calcification, it seems that there is strong justification for a policy of conservatism. Urinary tuberculosis is not a fulminating condition on the whole it is only slowly progressive and further vesical lesions, in general, present a high degree of recovery once the renal disease is removed. The progress of the condition lends itself to very precise observation; again, repeated examinations of the twenty four hour specimen provide clear indications for repetition of the cystoscopic and roentgenographic investigations.

Therefore it seems that if conditions in general are favorable and the patient is co-operative in the matter, so-called expectant treatment is permissible. Only one further point is to be emphasized that is, how permanent is the healing of renal tuberculosis? It will be noted that even in this small series there were cases in which healing occurred only to break down later on, and it was common experience in nephrectomy for gross tuberculosis to find areas of calcification indicating healing in the remote past, with recurrence of extensive destruction. It may nevertheless still be argued that in view of these considerations—case of control and slowness of progress—the tendency to later breakdown still does not invalidate the soundness of the conservative attitude in simple bacilluria. There was little support for it in the cases presented. Gross tuberculosis was found in each one submitted to nephrectomy and in 3 the old healing had broken down again of the conservatively treated cases 2 developed gross renal tuberculosis and in the others tubercle bacilli were still present in the urine.

JOHN A. LOER, M.D.

Ward, R. O.: Some Surgical Aspects of Urinary Bilharziasis. *Proc R. Soc. Med. Lond.*, 1945 39 27.

Bilharziasis is a disease which produces many important changes in the urinary tract and is of only for that reason worthy of the interest of urologists.

Examination of the urine. The most general method of making a diagnosis of bilharziasis hematuria is to examine the last drops of urine passed or the centrifuged deposit of the urine of the patient under a $\frac{3}{8}$ inch or $\frac{1}{8}$ inch objective. No staining is required. The ova with their terminal spines are easily recognized. In the late stages the sclerosed bladder may be palpable in an emaciated patient, and per rectum extensive induration may be found to involve the prostate and vesicles and all tissues at the bladder base and in the perineum.

The importance of cystoscopy in diagnosis. (1) A solitary examination of the urine for ova is a quite unreliable test, for ova are not continually released from the lesions of the mucosa. (2) Five consecutive morning specimens, the last few drops of the urine being collected and centrifuged will show either ova or red blood cells in about 85 per cent of the cases the latter being strong evidence in the mass examination of natives that bilharzia is present. (3) Even in the absence of ova or red blood cells the continual presence of pus or albumin in a native's urine means that a diagnosis of bilharzia is probable until it has been disproved. (4) Cystoscopy is the most accurate method of diagnosis in all active phases of bilharziasis. Moreover there are several characteristic vesical changes which persist when the active stages of the disease are past. It may be argued that cystoscopy does not reveal lesions of the kidneys and the urethral mucosa that must be admitted but it is probably very rarely that these tissues are affected without vesical involvement.

Cystoscopic appearances in renal bilharziasis. The earliest abnormality seen in the bladder mucosa is the appearance of patches of congestion which occur most commonly in the trigonal region these, however have no characteristics which enable a certain diagnosis to be made. Subsequent stages are specific.

The first of these stages is very typical. Bilharzial tubercles make their appearance. Each of these is about as large as the tubercle due to Koch's bacillus (to which it bears some resemblance) that is to say about the size of a pin's head. It is raised above the level of the mucosa and is surrounded by a narrow ring of congested vessels. It has a shining surface and a faintly yellow color. As it grows and dies the shine diminishes, and the yellow color remains and is sometimes intensified while the surrounding hyperemia becomes less or may disappear entirely. The bladder mucosa which lies around a collection of these tubercles is sometimes congested but it may be very little different from the normal. When an intense invasion by ova is in progress very marked bullous edema is often produced. It is difficult to say how much of this is a mere reaction to the ova and their toxins, and how much of it is due to venous blockage by the worms, but probably the former is the more important cause.

Calcification of the bladder tissues around the ova is a prominent feature in all severely infected long standing and untreated cases.

One local result of calcification is what is called sandy patches in the mucosa.

The process of calcification affects chiefly the sub-mucosa layer of the bladder wall. It is by no means necessarily accompanied by secondary infection, and on cystoscopy in such cases the bladder has often been clean. When this was the case it was usually very pale because of sclerosis and diminution of the vessels. This calcification forms a barrier in which many ova perish and through which others cannot work their way.

Another stage is the development of a bilharzial ulcer. This may be clean and without sloughs. It is usually single and Makar says that he has never seen this type of ulcer become malignant. More often secondary infection is coexistent, and in such cases an ulcer also usually a solitary one, has a sloughing base and marked cystitis is present.

Vesical papillomas due to bilharzia are common in Egypt. This is a true neoplastic condition and frequently malignant. In that country cancer of other organs is uncommon, and these growths are considered to be the result of the toxins of the ova. A bilharzial papilloma unlike a granulomatous mass with which it sometimes may be confused, is, of course, not to be cured by medical treatment. These growths do not have long fronds but are of firm consistency. Usually there are only 2 or 3 of them. The commonest variety of bilharzial papilloma met with in Egypt is of bulbous form and dark red color although in parts it has a grayish white appearance due to septic necrosis and to phosphatic deposits in the growth. These growths may spread and in rare cases involve the greater part of the bladder. Nodular infiltrating carcinomas are less common. In the series of 130 cases, 10 were of this variety. This variety has the characteristics with which we are familiar and follows the course common to all bladder carcinomas of this type.

In untreated cases the musculature of the bladder which is the seat of this disease, tends to be thickened partly because of hypertrophy and partly because of fibrosis due to the additional development of prostatic and urethral obstruction, resulting from bilharzial changes in those tissues. Despite such obstruction the bladder in these cases often remains contracted and this renders suprapubic cystotomy very difficult or impossible. Urinary fistulas which are a direct result of the disease produce the same result. They affect all parts, but particularly the floor of the urethral bulb and are often so numerous and extensive that when the male patient squats to micturate the perineal effect resembles the spraying from the rose of a watering can. These fistulas sometimes track widely.

Vesical calculi are met with in bilharziasis and in rare cases the ova have been found within the stones. These calculi appear to be composed of uric acid and oxalates, and are formed upon debris. Phosphatic calculi are very common when sepsis has become severe. Renal calculi are also encountered, although they are very much less frequent.

Ureteral obstruction of moderate degree is often encountered during the active stage of the disease. In such cases it will disappear when a course of treatment with antimony has had time to kill the worms and thus cause the acute reactive processes to resolve.

Chronic ureteral stricture is a very important and frequently insidious result of bilharziasis which we must be prepared to diagnose and to treat. It affects the lower parts of the duct for the upper portions lie in an area which is but rarely invaded by the worms. Most of the various pathological conditions which arise in the venical mucosa may also be encountered in the ureters, but stenosis is the common complication. Although it may sink into relative insignificance in the clinical picture of a native affected by advanced urinary bilharziasis, yet in such patients death from infected bilateral hydrophrosis is common. These strictures however are encountered in patients who appear at first sight to have recovered completely from the disease.

Dilatation of an established stricture of the ureter is best effected through an instrument of the McCarthy panendoscope type with some form of stiff ureteral dilator. Such a method when possible is very effective, more so it seems than in any other types of ureteral strictures and although the case requires further supervision the cure is often complete.

The author does not discuss the general treatment of urinary bilharziasis or of the later complications of the disease.

Tartar emetic remains the best drug for treatment, despite some unpleasant effects experienced by the patient during the period of administration. The course should amount to a total of 30 gr. and it must be intensive lest the parasites acquire a resistance to antimony. There are also some more recent preparations such as stibophenium antihomaline and foudain. These are administered intramuscularly; this is of great value in the treatment of the school children of the Delta. These preparations obviously have advantages when large numbers of troops are treated but they are not considered to be so certainly curative as is antimony sodium tartrate. Antimony first sterilizes the generative apparatus of the female worms and ultimately destroys them. It is not known just how certain is the effect upon those ova which have been deposited before treatment was begun.

It will be agreed that we must keep our eyes open for occasional cases of this disease. Not only officers but men of all three Services have been in the countries where this disease is endemic.

JOHN A. LORR, M.D.

Combes, F. C., Canizares, O. and Landy, S.: Lymphogranuloma Venereum. *Am J Syph.*, 1945 29 611

The problem of diagnosis of so-called latent forms of lymphogranuloma venereum has never been

solved and this inability to determine the presence or absence, or the degree of activity of the disease is a serious handicap. Patients considered cured discharged, and allowed to resume their normal activities frequently have a residual, small hard mass in the inguinal region which has been interpreted as a fibrotic reaction and a sequela of the reparative process but there is no proof at present that these patients are definitely cured and that they do not harbor dormant but viable virus in these nodes. The same problem exists in patients with aogenitrectal involvement. A test capable of detecting evidence of activity during these "latent" periods should be invaluable. The Frei reaction persists after convalescence for an indefinite time, and is not so indication of the degree of activity. The complement fixation test of Grace Shaffer and Rake is not yet standardized and perfected.

There are definite changes in the blood serum proteins of patients with lymphogranuloma venereum, chief of which is a hyperglobulinemia. The formol gel test is predicated upon the presence of an increase in seroglobulins, and is not specific for any disease. A rapidly positive formol-gel test indicates a high seroglobulin. The authors made formol-gel tests and albumin-globulin ratio determinations on 42 cases of lymphogranuloma venereum and formol-gel tests on 307 controls. Of the 42 known cases of lymphogranuloma venereum, 38 had positive formol-gel reactions after the disease had been present for three weeks and these were consistently positive after the disease had been present for several months or years especially in active anorectal cases. Of the 307 controls only 6 gave positive reactions. The authors conclude that the formol-gel test is a simple reliable bedside procedure of value to determine the presence of hyperglobulinemia in lymphogranuloma venereum. There was a tendency toward a return to normal after a clinical cure in 85 per cent of the cases. Hyperglobulinemia is of some value in determining the degree of activity of lymphogranuloma venereum and formol-gel reactions and albumin globulin ratios should be determined in all patients as an aid in treatment and for indication of biological cure.

DAVID ROSENBLUM, M.D.

Magnuson, H. J., and Eagle, H.: The Retardation and Suppression of Experimental Early Syphilis by Small Doses of Penicillin Comparable to Those Used in the Treatment of Gonorrhea. *Am J Syph.* 1945 29 587

The widespread use of penicillin in the treatment of gonorrhea has raised several problems with respect to the effect of such therapy on concomitantly acquired syphilis. Since the doses of penicillin usually employed (100,000 to 200,000 units) are sufficient to cause the disappearance of treponema pallidum from primary lesions which were previously dark field positive and since these doses are subcurative for established syphilis in man, it is conceivable that such therapy given during the incubation period of syphilis might (a) prolong the incubation period

(b) suppress the symptoms and result in an asymptomatic infection, or (c) actually abort the syphilis. A number of cases have been reported in which penicillin therapy for gonorrhea has rendered the diagnosis of syphilis difficult either by making a pre-existing but unrecognized primary lesion darkfield negative or by delaying the appearance of symptomatic or serologic evidence of the disease.

The authors demonstrated that, in rabbits small doses of penicillin have definite suppressive effects on the development of the lesions of early syphilis. The smaller the spirochetal inoculum the more pronounced is the suppressive action of penicillin and the suppressive action is maximal when the penicillin is given before the seventh day of the illness. When penicillin fails to prevent the appearance of the primary lesion, it regularly causes a significant prolongation of the incubation period probably because most of the organisms have been killed by the penicillin and the few residual organisms take more time to develop a primary lesion. In some cases the primary lesion and the infection were aborted. In general, the smaller the inoculum and the earlier treatment was begun the greater was the proportion of inoculated sites at which lesions failed to develop.

Clinically doses of penicillin comparable to those used in the treatment of gonorrhea may materially modify the course of syphilis simultaneously acquired in many of the cases the incubation period is merely prolonged and the patient may no longer be under medical supervision at the time of development of the lesion. Patients treated for gonorrhea with penicillin should be followed up both clinically and serologically for a minimum period of 4 months after exposure in order to minimize the possibility of delayed primary lesions or clinically asymptomatic syphilitic infections, and the patients should be specifically advised of this danger.

DAVID ROSENBLUM, M.D.

Joishi, L. B.: Urinary Calculi. *Ind J Surg* 1945 7: 69

The author's article may be summarized as follows:

1. The uriniferous tubule probably acts on the principle of a flush.

2. All deposits in the kidney which are insoluble pigments, and casts could be seeds of urinary stones.

3. Sodium chlorides and sulfates have the property of preventing the formation of urinary stones.

4. The tertiary rock map of the world in association with the big rivers resembles the map of distribution of urinary stones.

5. The scarcity or abundance of water has no effect on the incidence of urinary stones.

6. The temporary hardness of water is one of the most important causes of urinary stones.

7. The envelope shaped crystals seen in oxaluria are composed of potassium oxalate and not of calcium oxalate.

8. In cases of phosphaturia, gastric analysis often reveals achlorhydria or hypochlorhydria.

9. Calcium sulfate is a fairly common constituent of urinary stones.

10. The age incidence of urinary stones probably depends on the general standard of health and care of children.

11. Town people acquire more urinary stones (than the rural population) if the water is not chlorinated or filtered.

12. Whales sailors of old days, and long term jail inmates have no urinary stones.

JOHN A. LOEY, M.D.

Wilson, J. G., Benjamin, J. A. and Leshy, A. D.: Study of Experimental Urinary Calculi: Methods for Producing and Preventing Calcium Formation in the Bladder and Urethra of Albino Rats. *J Urol* 1945, 54: 393.

Newborn albino rats were injected thrice weekly with 0.1 mgm. of estradiol dipropionate for a period of from 3 to 4 weeks so that the total dosage was either 0.6 or 1.2 mgm. Seventy-eight injected animals were fed on a commercially prepared stock ration which did not vary much from other such preparations, all of which are of a high mineral content. Thirty-four animals were fed on a low mineral diet which was of sufficient amount to be compatible with normal growth and reproduction. Beginning at 30 days of age periodic examinations by palpation of the bladder and the urethra, and by x ray were made to detect the presence of stone. Urinary infection was ascertained by culture and by the ability of the organisms to split urea. The urine pH was determined on each specimen.

Forty-five animals were fed on a high mineral diet until the presence of stones was ascertained, death ensued, or until 15 months of age was reached. In this group there were 39 male animals, 21 (52.6%) of which developed vesical or urethral calculi between the first and the fifteenth months, and during this period none of the females or control animals developed stones.

In order to determine the accuracy of x ray and palpation as a method of demonstrating urinary calculi 23 male and 12 female animals were fed high mineral diets after weaning and were sacrificed at intervals for autopsy. The results confirmed the opinion that the stones began to form sooner than they could be detected by means other than autopsy. The authors state that if all the males had been permitted to live to the age of 150 days, it may be estimated that at least 20 (47.6%) would have yielded stones at autopsy as contrasted with 29.5 per cent of known cases of lithiasis at this age in the previous group of male animals. Also 1 female in the autopsied series was found to have stones in the bladder. There was no difference in the incidence of stones in the group receiving 0.6 or 1.2 mgm. of estradiol dipropionate.

Cultures of bladder urine of injected males showed infection whether or not calculi had formed.

Specimens from 13 older males yielded *escherichia coli* in 10 and the remaining 3 showed a nonhemolytic streptococcus alpha hemolytic streptococcus and a mixed streptococcus fecalis and *escherichia coli*. No correlation existed between the infectious agent and the age at which the host formed calculi and the urine of animals having calculi was always more or less alkaline. Urinary infection always preceded calculus formation.

Seventeen of the 24 males with infection showed focal sites of infection in the bulbourethral gland and occasionally in the prostate seminal vesicles or bladder wall but rarely in the kidney. In the injected females 9 of the 20 had infected bladder urine, but it is of particular interest that at necropsy not a single instance of focal infection was found in the urinary tract. Focal infections were observed in the atrophic uteri and oviducts in 8 of 28 cases but were not always associated with infection in the urine.

All stone bearing males revealed some urinary tract abnormality with a variable resultant stasis. The most persistent finding was obstruction between the bladder and urethral sinus which seemed occasioned by the common finding of an abscessed bulbourethral gland. Then too the sectioned urethra at this point of several young estrogen injected rats revealed great numbers of desquamated cornified cells, often in the form of large plaques suspended in the lumen. No urinary obstruction was found in the female animals except in the one which developed a stone.

Nineteen males and 15 females were injected during the first 2 weeks of life. They were fed a low mineral diet and sacrificed after a period of 180 days. Two males in this group revealed calculi the other animals were free of stones. The stone incidence in this group was reduced from 82.8 per cent to 10.5 per cent by feeding a group of injected animals on a low mineral diet.

The authors concluded from their experimental work, that (1) infection preceded stone formation (2) alkaluria was characteristic of stone forming animals (3) neither the type of organism nor its urea splitting potentialities was related to the urine pH or calculus formation (4) urinary stasis accompanied calculus formation but was not necessarily responsible, and (5) lithiasis so produced could be materially reduced by a diminished mineral diet.

ROBERT LICH, JR., M.D.

Benjamin J. A. Wilson J. G., and Leahy A. D.: Study of Experimental Urinary Calculi; Quantitative Microchemical Spectrographic, and Citric Acid Analyses of Albino Rat Calculi, with a Preliminary Apatite Report. *J. Urol. Balt.*, 1945 54 516.

The stones analyzed in this paper were produced experimentally in rats by feeding them on a high mineral diet and subjecting them simultaneously to injections of estradiol dipropionate. The calculi varied in size from 1 to 6 mm.

Ninety per cent of the stones showed a composition of magnesium ammonia, phosphate, and moisture. Calcium was found in small amounts as was citrate and carbonate in only minute amounts. These results were confirmed by spectrographic analysis. It was found that carbonate-apatite was a common constituent of the stones studied.

The principal chemical constituents in this series of calculi were reasonably constant, irrespective of the size, shape, or site of origin. Bladder calculi as compared to urethral calculi were white in color rather than brown but in both, magnesium ammonium phosphate hexahydrate was the principal compound, though the urethral calculi contained calcium and more phosphate.

Spectrographic studies confirmed the findings, and occasionally revealed small amounts of sodium, iron, aluminum, and silicon. ROBERT LICH, JR., M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Jönsson, G.: Has Acute Hematogenous Osteomyelitis Become Less Common and Less Severe? *Acta chir scand* 1945 93 533.

The author has gone through the material of 30 years (1913-1941) of hematogenous osteomyelitis seen at the Surgical Clinic in Lund. This followed a suggestion made during the last decade that acute hematogenous osteomyelitis has changed in character in that it has become less severe with the years and at the same time a disease that occurs less and less frequently.

The material consists of 135 cases. Its distribution regarding sex and age corresponds to the figures usually given. If the cases are divided into 5 year periods one finds that the smallest number has been treated during the last period during which no death occurred. The study reveals that a smaller number of complications have occurred during the last 5 year period as compared with earlier ones. The duration of treatment has been considerably shorter during later years. During recent years the patient's condition on admittance to the clinic has been much better than formerly. In nearly all of the cases the treatment has been operative. Serum or chemotherapy has not been employed in any of the cases.

The Lund material gives one the very definite impression that the disease has had a considerably more benign course during later years than previously, with fewer deaths during the septic initial stage, fewer complications during the later stages, and a more rapid course of healing.

Buchman, J., and Blair, J. E.: Penicillin in the Treatment of Chronic Osteomyelitis. A Preliminary Report. *Arch Surg* 1945 5 8.

The authors conducted a clinical and bacteriologic study of the results of treatment of chronic osteomyelitis with penicillin, with and without surgical intervention. There were 68 lesions in 47 patients.

Some of the conclusions drawn are tentative because of an insufficient period of follow-up but others are sufficiently clear and certain.

The use of penicillin alone, whether given by local application or intramuscular injection, is totally ineffective in chronic osteomyelitis. If after preoperative and postoperative administration of penicillin and thorough saucerization the resultant wound is allowed to heal by granulation the results are not materially influenced by the addition of penicillin to the treatment. The same type of treatment and delayed primary closure (rather than allowing healing by granulation) constitute a considerable improvement over previous methods. The treatment of chronic osteomyelitis by preoperative and post-

operative administration of penicillin, thorough saucerization of the focus of infection and primary closure of the resultant wound gave extraordinarily good results in 23 of 27 patients, but the authors state that the postoperative period of observation was insufficient.

Of the tuberculous lesions of the bones and joints secondarily infected with *coagulase positive staphylococcus aureus*, treated by the preoperative and postoperative administration of penicillin, and subjected to thorough saucerization and primary closure a limited number presented primary healing over a short period of observation.

A distinct advantage of primary closure is the reduction in the incidence of secondary infection which so frequently (80%) complicates delayed closure. *Staphylococci* persisting in wounds healing by granulation or delayed closure develop increasing resistance to penicillin.

DANIEL H. LEVINTHAL, M.D.

Altmeier, W. A., and Reineke, H. G.: Roentgenographic Interpretation of Acute Hematogenous Osteomyelitis Treated with Penicillin. *Am J Roentg* 1945 54 437.

The introduction of penicillin has completely altered the management of acute hematogenous osteomyelitis. The rapid control of the general and local infection makes an emergency surgical decompression of the area of the bone involved unnecessary except in the fulminating cases. Operative intervention as a rule, is limited to incisions and drainage of abscesses of the soft tissues and to removal of sequestra. Because of this milder course the bone changes which follow show a different appearance from that which is known to characterize the subsequent stage of acute hematogenous osteomyelitis and therefore roentgen interpretation merits our attention.

During the past 27 months the authors observed 52 cases of acute hematogenous osteomyelitis treated with penicillin. In 44 of these the osteomyelitis was localized in the long bones, in 4 to the flat pelvic bones, and in the remainder to both. The etiologic agent was represented by the hemolytic *staphylococcus aureus* in 42 cases, the nonhemolytic *staphylococcus albus* in 3, the hemolytic *streptococcus* in 1, and the *pneumococcus* III in 1 and it remained undetermined in 4 cases.

All of the cases were treated with penicillin, although in 28 limited amount of sulfonamides were given prior to the penicillin. The early cases received less than 800,000 units of penicillin, but eventually a total of 1,500,000 units given intravenously or intramuscularly at the rate of from 15,000 to 25,000 units every 3 hours proved the most desirable dosage. In some cases it was administered by intravenous drip at the rate of from

15 to 30 drops per minute in the form of 2 000 c.c. of physiological saline solution containing 30 000 to 80 000 units of penicillin. The dose was reduced when it became apparent that the infection was controlled.

The results were remarkable. All patients recovered except 1 so that the mortality was only 19 per cent. The period of morbidity likewise was strikingly reduced.

Clinically the cases were divided into four groups.

Group 1 The correct diagnosis was made within the first 2 or 3 days and adequate treatment started immediately. The results were truly excellent.

Group 2 The diagnosis and treatment were moderately delayed. Here the infection was brought under control in 2, 3, or more days and local soft tissue abscesses developed more frequently.

Group 3 The diagnosis and treatment were delayed for from 7 to 10 or more days when the infection was unusually severe, local destruction of bone became very great, and soft tissue abscess formation and sequestration occurred in most cases. In this group the infection was arrested with more difficulty and rather prolonged treatments were necessary. Small abscesses were treated by aspiration, large ones by incision and drainage and the sequestra were removed.

Group 4 The osteomyelitis was so fulminating that surgical intervention still constituted an emergency measure. In such instances penicillin at the rate of 15 000 units every 1 to 3 hours was given preoperatively and postoperatively.

The roentgen changes in the various groups were interpreted as follows:

In group 1 the bone alterations were minimal consisting of areas of localized periosteal reaction, small areas of patchy decalcification of the underlying cortex, little or no evidence of sequestration and ultimate reconstitution of the bone. In 3 cases the roentgen findings were entirely negative.

In group 2 the changes likewise were minimal at the beginning of the treatment, but after a week or so periosteal reaction and patchy demineralization of the underlying cortex became evident. These increased in extent and degree, becoming most marked in from 1 to 3 months after the onset of the infection. Then, recalcification followed with rapid return to normal. Sequestration occurred only occasionally. In group 3 there was extensive bone destruction at the start of the penicillin therapy. This increased on subsequent examinations. Small sequestra were absorbed spontaneously and larger ones acted as autogenous grafts. Rarely was the sequestrum discharged. Recovery followed eventually.

In group 4 the bone destruction was very extensive due to the severity of the infection.

The authors include detailed clinical histories of 6 typical cases and use serial roentgenograms to illustrate the course of the disease under the influence of the penicillin therapy and the good results obtained.

T. LEUCUTA, M.D.

Lewis R. W.: Differential Diagnosis of Tuberculosis in Joints of the Extremities. *Am J Roentg* 1945 54 320.

In 1924 Phemister described the principal criteria of differential diagnosis between tuberculous and nontuberculous suppurative arthritis. These criteria still stand although they are not as widely employed as their importance warrants. Therefore, the author wishes to restate them and add some new ones of his own.

According to Phemister in pyogenic arthritis there is early narrowing or disappearance of the joint space because of the fact that the articular cartilage is killed and broken down first at the points of contact and pressure of the opposing articular surfaces. For the same reason the earliest bone destruction occurs in the opposing or weight bearing portions of the articular surfaces. In contrast to this in tuberculous arthritis the joint space is preserved for months or years since the earliest destruction is peripheral along the surfaces where tuberculous granulations can grow. Likewise the earliest bone destruction is not on the contiguous opposing bony surfaces but about the margin of the weight bearing surfaces.

To these points the author adds (1) in acute pyogenic arthritis osteoporosis about the joint is rapid and marked whereas in tuberculous it is usually lacking; (2) acute pyogenic joints show a distinct tendency toward repair and ankylosis features which are customarily absent in tuberculous; and (3) in tuberculosis the adjacent muscles often are markedly atrophic which is not the case in acute pyogenic infections.

Unfortunately however the picture is not always so clear. There are many variables due to difference in virulence of the invading organisms and reaction in the host. Another confusing factor is the apparent difference in the roentgen manifestations of certain joints as for example the hip joint, in which the criteria of Phemister are seldom observed and therefore the differential diagnosis must be more circumspect. Still another difficulty is created by the rather infrequent but entirely different form of tuberculous the so-called *caries sicca*.

The differential diagnosis of tuberculous of joints from other diseases than acute pyogenic infection as a rule, is quite easy although lymphatic leucemia and probably some other conditions may simulate tuberculous arthritis.

Several illustrative cases are presented to prove the various points.

T. LEUCUTA, M.D.

Simon H. E.: Muscle Hernia, with Report of 6 Additional Cases in the Arm and Leg. *Mil. Surgeon* 1945 97 369.

Muscle hernia or protrusion of muscle tissue through a defect in the overlying fascia is rarely recognized in civilian life. In military service, it is frequently observed and often symptomatic. The author presents 6 case reports to add to the 163 cases of muscle hernia described in the literature.

Three of the patients developed the hernia in the lower extremities and 3 in the upper. The condition occurs almost invariably in the third and fourth decades and is practically limited to males. Three types are recognized.

The congenital type. No case has been found in the literature which was primarily of congenital origin.

The traumatic type (a) Direct trauma as laceration, contusion or puncture wound (b) Indirect due to a single powerful muscle action.

The idiopathic or spontaneous type. Due to increase in muscular development and activity.

The anterior tibial muscle is the one usually involved although hernia may appear anywhere. It appears as a circumscribed semitransparent swelling which varies in size according to the position of the part involved and the state of contraction of the underlying muscle. Typically the swelling increases in size with muscle relaxation and is reduced by pressure which reveals a circumscribed defect palpable in the fascia. Aching pain or local tenderness may be present as well as muscle cramping and increased fatigability.

Hernias due to direct trauma appear immediately or several months after the resumption of muscle activity. They may reach a diameter of 6 cm. or more. Pain and discomfort are more pronounced.

Those due to indirect trauma appear abruptly after the accident.

The idiopathic type is usually small and not infrequently multiple and bilateral and occurs almost exclusively in the legs. It may be mistaken for localized varicosities, arteriovenous aneurysms, lipomas, myomas, or cysts.

Treatment is indicated when the defects are large and deforming, or produce symptoms that are interfering with normal activities.

Temporary symptomatic relief may be attained by elastic pressure bandages. For permanent cure surgery is usually necessary. This consists of careful exposure of the fascia defect and closure by overlapping and suture of a fascial transplant with lapping and suture of an interlacing strip.

When the defect is large, a fascial transplant may be used either as a patch or an interlacing strip—the patch is preferable. Pressure immobilization for 3 weeks is maintained for 3 weeks. Elastic bandages or cast is maintained for 3 weeks postoperatively after which activity is gradually resumed.

VANAN C. TUNNEY, M.D.

Wyatt, H., McWhirter, R., and Johnson, H.: A Symposium on Ankylosing Spondylitis. *Brit. J. Radiol.* 1945 18 306.

In this symposium Wyatt of the Ministry of Pensions gives an account of the results of the treatment of pensioners suffering from ankylosing spondylitis by deep x ray therapy and massage. After the last war the disease was observed rarely but in this war it has become much more common. The author supervised the treatment of about 100 cases. The present scheme is to arrange x-ray treatment on 5 consecutive days in a week, the first course gen-

erally lasting 3 weeks. This results in much relief of pain although stiffness persists. The treatment is repeated at intervals of from 2 to 3 months. In the interim suitable exercises are given in a Ministry Clinic, sometimes preceded by some form of heat, such as radiant heat or diathermy. The exercises are given by masseuses. In the main, the lies in relaxation of spasm and posture and increased mobility of the spine and thorax. Breathing exercises are important and are done in various positions. After all treatment is completed the men are encouraged to return to work. The author rarely hears from such men, unless it is to report that they are proceeding satisfactorily.

McWhirter of the Edinburgh Royal Infirmary gives a clinical discussion of the subject. To avoid confusion he assumes that ankylosing spondylitis is synonymous with Marie-Strumpel type of spondylitis ankylopoietica.

It is important that the disease be recognized early since, unfortunately little or nothing can be done in the advanced stages.

The author's experience covers 165 cases, of which 100 were in males. As a rule, the onset of the condition occurred during the third decade of life.

The earliest symptoms are fleeting pains in the back and hips followed by more constant pains localized in the lumbar region. Then the back becomes stiff and there is some deterioration of the patient's general health. Chest expansion becomes restricted and the sedimentation rate is raised. X ray examination shows blurring and irregular destruction of the sacroiliac joints, with sclerosis of the bone adjacent to the joints. The spine at this stage shows little or no change.

As the disease progresses the posterior articular surfaces of the spine become narrowed and the margins of the vertebral bodies become sharp. Still later the anterior and lateral column ligaments become ossified and eventually the entire spine assumes a bamboo appearance. Less well recognized changes are irregularities of the ischial tuberosities, ilium, symphysis pubis, and of the sternum. Some of the joints of the extremities may also become involved.

The etiology remains unknown.

The treatment consists of a combination of deep x ray therapy and various orthopedic measures. The x ray therapy is localized to the sacroiliac joints and the whole length of the spine. The factors are 250 kv., 1 mm. of steel, and 500 roentgens of skin dose on all fields given over a period of two weeks. This produces a reaction not exceeding dry dermatitis.

According to the x-ray findings, patients are classified into (a) early, (b) moderately advanced, and (c) advanced cases. Patients in the first two classes are put to bed with fracture boards under the mattress for several weeks. Deep breathing exercises are started first, then other exercises are carried out with the patient on his face until the lumbar

stiffness is overcome. After the patients are up a light brace is fitted in group *a* and a light plaster jacket in group *b* which may be worn from 6 to 12 months or longer.

The results are encouraging. In group *a* the patients have remained well for as long as 7 years. In group *b* relief of pain and general improvement are often obtained for varying periods. Even in group *c* some relief of pain and unless the spine is completely ankylosed a partial correction of the deformity is possible.

Johnson of the Charterhouse Rheumatism Clinic in his part of the symposium pays special attention to the prognosis of spondylitis in relation to treatment. He takes exception to the very gloomy view as expressed in Volume 2 of the British Encyclopedia of Medical Practice (1936). The books of the Charterhouse Rheumatism Clinic contain reference to some 500 spondylitis patients. A review of these records reveals an entirely different aspect.

The disease is almost certainly an infection possibly due to a form of tubercle, although some regard it as a disease of the endocrine system. In many instances breakdown of the natural resistance seems to be determined by physical overstrain or by an accident. In the untreated case the prognosis depends on this breaking down of the natural resistance.

Some years before his death Scott introduced the wide field method at this institution for the x-ray treatment of ankylosing spondylitis. The principle behind this method was to stimulate the natural resistance. The results were so satisfactory that the method is being continued. An average dose of 50 roentgens twice a week is given but in some cases it is reduced to 10 roentgens to avoid all possible unpleasant reaction. Hemoglobin estimation and special sedimentation tests are often necessary guides. The total dosage in 1 year is not allowed to exceed 1,500 roentgens.

If x-ray treatment cannot be given, stock vaccines of streptococci and staphylococci given weekly are often a good substitute. Other forms of stimulus, such as cold or even ultraviolet ray baths, may be of value. Potential foci of infection should be removed.

Under such care the prognosis as regards the continued capacity to earn a living is good. Nearly all patients of the Clinic are able to hold down ordinary jobs. Neither are they dissuaded from marriage. There is no proof that the disease is hereditary.

T. LECUIT, M.D.

Hooker D. H.: Brachymetopody. *Bull Johns Hopkins Hosp.*, 1945 77: 399.

Brachymetopody is a condition in which certain digits of the hand or foot are shorter than normal. It is caused by abnormally short metacarpals or metatarsals, respectively. Three cases are presented in which there were short fourth toes.

The chief complaints were metatarsalgia, callosities over the metatarsal heads and relaxed longitudinal arches. The condition apparently was present at birth. All of these patients began having

Fig. 1. Shortening of otherwise normal fourth metatarsal bones, each metatarsal being about 1.5 cm. shorter than the adjacent third metatarsal.

trouble with their feet after basic training in the Army.

A hereditary factor was established in every one of these cases. The treatment consisted of arch supports, metatarsal pads, weight reduction and limited physical activity.

A congenital origin of brachymetopody is suggested by the author.
GEORGE I. REINE, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Knight, M. P., and Wood G. O.: Surgical Obliteration of Bone Cavities following Traumatic Osteomyelitis. *J. Bone Surg.*, 1945 27: 547.

High velocity war missiles have not only contributed many cases of osteomyelitis of the long bones but have furnished the orthopedic surgeon with many massive soft tissue and bone defects. Since skin and muscle defects over the long bones unequivocally interfere with bony repair the authors have devised a new approach for the expeditious obliteration of such cavities. It is apparent that if left alone, these defects would prolong rehabilitation and increase morbidity. To expect bone growth to ensue in the presence of infection, granulation, or even scar tissue, is indeed a bizarre expectation. Furthermore, bone does not show any demonstrable evidence of regeneration beneath adherent split thickness grafts as the cavities remain essentially the same size for an indefinite period of time. Previous efforts to obliterate septic cavities by anti-septic paste fat muscles and pedicle grafts have also proved unsuccessful.

The authors present a small series of 33 cases which were operated upon in three stages: (1) thorough sequestrectomy and excision of scar, (2) early split skin grafting and (3) bone grafting followed by immediate application of a full thickness pedicled graft.

The first stage is that of sequestrectomy and preparation of the cavity. All extracapsular soft tissue must be excised. Exposed bone or cartilage. If the defect is near a joint must be saucerized in its entirety. The wound is then packed with vaseline gauze and the limb is encased in a cast. At the end of 5 days the wound is inspected and if an exuberant granulation is noted on the bony cavity a split grafting operation is done to convert the compound wound into a closed one.

The second stage comprises the application of a split thickness skin graft. The recipient area is curetted of any nonviable or granulation tissue, and a split thickness graft from 0.10 to 0.16 of an inch is obtained and placed over the defect. A pressure dressing (Koch's) is applied on the wound. Immobilization is effected by a splint or cast. Chemotherapy consisting of penicillin or sulfonamides is administered for 3 days. Under this regime from 80 to 95 per cent skin take has been observed.

The third stage consists of obliteration of the bone cavity with autogenous bone chips. The principal factors of this stage are:

1. Planning of a suitable full thickness covering for the defect.
2. Complete excision of the split thickness covering from the depth of the saucerized bone defect.
3. Procurement of sufficient bone chips from the iliac crest or other suitable sites to fill the cavity completely.
4. Covering of the chip filled cavity with skin and subcutaneous tissue without skin tension and placing the suture line on sound bone.

Osteogenic consolidation of the defect can be further enhanced by curetting the cavity and opening both ends of the medullary canal. A pressure dressing of machinist's waste is again applied. Sutures are removed in 6 days. Chemotherapy is continued for from 3 to 5 days, and immobilization is maintained until bony union is obtained.

Accompanying the article are many excellent photographs of the technique and numerous roentgenograms of the bony defects involving the tibia and femur.

The complications encountered in the 33 cases were hematoma in 2 tibias, suppuration in 1 tibia, and a draining sinus adjacent to the operative site in a femur.

SAMUEL L. GOVERMAN, M.D.

GILLIE, L. I. Nearthrodis of Humerus Shaft for Amputation at the Elbow. *Brit. M. J.* 1945 2: 686.

The author describes a new operation for making a joint in the shaft of the humerus for cases of amputation at or near the elbow joint. According to this article it is no longer necessary to amputate an arm at the orthodox site of election, i.e. 7 or 8 inches below the tip of the acromion. It is to be remembered that the forearm resected at, above, or below the elbow joint can now be fitted with a useful prosthesis.

As its purpose the operation is designed to accomplish two distinct functions (1) to conserve the

muscular power of the flexors and extensors of the forearm and to harness that function and (2) to make a new joint in the shaft of the humerus at least 4 in. below the shoulder which should possess the property of complete extension and a varying degree of flexion.

The author has performed 24 such operations.

The first 8 of these necessitated a second intervention for removal of increasing ankylosis of the joint in order that bony union of the new joint be prevented. The technique was altered as follows:

1. A posterior muscle splitting incision from 3 to 3 3/4 inches long was used.
2. From 1 1/4 to 2 inches of the humeral shaft were removed with a gigli saw.
3. The ends of the bones were bevelled at an angle of 45 degrees in front to permit the maximum degree of flexion.
4. The medullary cavity of the bones was curetted and packed with bone wax.
5. The bone ends were fulgurated and sulfanilamide implanted in them. This step is considered important by the author as it vitates osteogenesis.

The postoperative management consists of the application of a straight plaster of Paris cast for 3 weeks, active and passive motion of the new forearm, and the application of a figure 8 crepe bandage.

In addition to several illustrations, the article contains 5 detailed case reports depicting the technical periparties encountered in the original operation and their solutions.

The results in 10 cases show uniform function of flexion and ability of the patient to touch his face and back of the neck without pain. Six of the 21 patients have acquired varying degrees of active flexion and the condition is still improving. Functional results in the first 8 cases (operated twice) were not noted.

SAMUEL L. GOVERMAN, M.D.

FRACTURES AND DISLOCATIONS

ELLA, J. S. Wounds in the Region of the Hip Joint. *Lancet*, Lond. 1945 249: 490.

The unsatisfactory results in a group of 44 wounds of the hip-joint and high femoral fractures treated in the base hospital attended by the author prompted a review of the methods used and led to the suggestion of improvements.

In 1914 to 1918 the mortality in this group was 60 per cent, accounted for largely by visceral injuries and a stiff hip with shortening and often persistent draining sinuses was accepted as the usual result. Recent Russian writing advocates radical surgery with early resection of the joint or disarticulation at the hip, to control toxemia.

The patients were received from 1 to 4 weeks after injury and had either obvious wounds of the hip joint or fractures in the area of the neck or trochanter with doubtful penetration of the hip joint. Twenty two patients had been or still were toxic

when received. All had been explored and foreign fragments had been removed including many bone fragments. Plaster spicas or Thomas splints were used for transportation and usually changed en route at the receiving hospital where some wounds were re-explored. Systemic administration of sulphonamides and penicillin was done routinely. The best hospital employed skeletal traction in Thomas splints and plaster fixation about equally. Sequestrectomies and 5 major drainage operations of the Girdlestone type were done.

Ankylosis of the hip occurred in 13 of the 16 cases in which the hip joint became septic. In 16 patients the wounds were unhealed at 6 months. Six patients had 1 inch or more of shortening.

Slow healing is due to inadequate primary drainage which makes delayed primary suture impossible and later to failure to recognize early the need for sequestrectomy or drainage of hidden abscesses. The use of penicillin masks the presence of undrained pockets and thus must be remembered in appraising the situation.

The shattered femoral head must be removed early to facilitate healing.

Shortening is inevitable in head and neck fractures but traction rather than plaster immobilization overcomes the tendency toward bowing and shortening in trochanteric fractures. Early knee motion is of great importance and need be delayed only when the desire to encourage hip fusion requires plaster immobilization rather than traction in a Thomas splint.

No living limb was lost in this series but in retrospect, morbidity might have been reduced by the knowledge gained and summarized here. Roentgenography before primary treatment is desirable to determine the status of the fracture, especially as to whether the femoral head is involved. Bone fragments should not be removed freely unless they are all or part of the femoral head. Rectal examination is essential to help establish the extent of possible intrapelvic injuries. A minimum of skin should be excised—no skin should be sutured—and a plaster spica should be used for transport. Systemic chemotherapy of course is used early and a "booster" dose should be given again before each change of cast or other manipulation to inhibit flare up of the infection.

Adequate later treatment necessitates removal of the cast and careful estimation of the patient's general condition with reapplication of the plaster spica only when ankylosis of the hip is desired. Constant vigilance for abscess formation or the presence of foreign bodies or sequestra, with prompt surgery will prevent persistent sinus drainage and lessen the morbidity. Early appreciation of the cases requiring radical treatment for deep seated infection, and prompt surgery of the Girdlestone type will save life and reduce morbidity. In the author's experience the end result of this treatment has been satisfactory.

FRANCIS C. BREWSTER, M.D.

Godoy Moreira, F. E. Difficult Fractures of the Neck of the Femur Treated with the Stud Bolt Screw. Simplification of Technique. *J Bone Surg* 1945 27 595.

In July 1940 the writer reported a technique for treating ununited fractures or otherwise difficult cases of fracture of the neck of the femur with the stud bolt screw. Since then the technique has been simplified. A hand drill has been substituted for the motor drill and the hard cortex is perforated by a hand driven burr preliminary to the insertion of the stud-bolt screw.

Eighty patients have been treated by this technique with excellent results and 8 case reports are presented illustrating that good union and function may be obtained. One patient, a 65 year old female was operated on 2 days following fracture of the femur. Four months later she had perfect union with normal function. The remaining 7 patients sustained fractures from 3 to 18 months before operation, the youngest being 40 and the oldest 70 years old. Of the 7, 6 obtained good union and perfect function while in 1 a 70 year old male, nonunion persisted but the patient was able to walk 3 miles easily. This good result is attributed to achieving solid osteosynthesis by means of the screw. In 2 instances osteotomy was performed at the same operation as an aid to union.

A short plaster spica is applied to the knee 20 days after operation and the patient is permitted to walk. The spica is removed 40 days afterward.

RUDOLPH S. REICHER, M.D.

ORTHOPEDICS IN GENERAL

Howard J. E. Parson W., and Bigham, R. S., Jr.: Studies on Patients Convalescent from Fracture. The Urinary Excretion of Calcium and Phosphorus. *Bull Johns Hopkins Hosp.*, 1945 77 391.

The calcium and phosphorus metabolism with special reference to Ca⁺⁺ concentration in the urine was studied in a group of 17 patients. Thirteen patients were convalescing from femoral and tibial fractures and 4 were studied before and after femoral osteotomy for slipped epiphysis.

This study was made in an attempt to explain two frequently observed conditions in recumbent orthopedic patients: (1) nephrolithiasis and (2) a lack of lime salts in the bones of limbs immobilized for long periods of time.

A steady rise in the calcium output in the urine was noted. It reached its maximum approximately 1 month after injury. The peak of excretion of calcium was maintained for an indefinite period. It usually began to fall when the immobilization was discontinued.

A similar pattern of urinary calcium excretion was observed in patients who had had a femoral osteotomy. The peak of calcium excretion, however, was reached much earlier. In patients who had suffered a fracture a rapid breakdown of protein occurred

with the excretion of large amounts of nitrogen. The maximum amount of urinary excretion of nitrogen was reached in from 5 to 7 days. It subsided in from 25 to 40 days.

Maximal excretion of calcium in the urine occurred in every instance at a time when the urinary output of nitrogen had returned to normal. The same reciprocal relationship between maximal diuresis of calcium and nitrogen had been observed in patients subjected to femoral osteotomy.

The type of injury (simple or compound fracture) and the patient's age, height, and weight or bony structure (heavy or light bony frame) had no bearing on the urinary output of calcium. The increase or decrease of water intake had no influence on the amount of calcium output in the urine. Alkalinization, sulfadiazine, or sulfathiazole did not change the level of the calcium excretion.

Large shifts in dietary calcium affected the urinary output of calcium very little. An increased or diminished intake of calcium in the form of calcium lactate had a somewhat greater influence upon the calcium diuresis than the intake of calcium in the form of milk.

Vitamin D₂ (calciferol) in varied doses, with or without an increased intake of calcium, did not significantly change the calcium excretion in the urine.

The rise and fall of intake of inorganic phosphorus showed similar changes in the urinary output of phosphorus.

The blood constituents of the patients showed no significant changes in the hemoglobin, red blood count, blood volume, calcium and phosphorus levels, and alkaline phosphatase concentration.

The theory that a decreased blood supply causes increased bone density and that hyperemia of the part results in skeletal rarefaction is challenged by the fact that reduction of the blood supply causes atrophy of the bone supplied. Unilateral lumbar sympathectomy in children caused the leg on the same side to improve its growth in most instances. This influence on the growth of the leg is exercised by the control of its blood supply. There is experimental evidence that venous obstruction accelerated fracture healing by speeding the formation of callus.

GEORGE I. RANE, M.D.

Balboni, V. G., Shapiro, I. M., and Kydd, D. M.: The Penetration of Penicillin into Joint Fluid following Intramuscular Administration. *Am. J. M. Sc.* 1945 50 588.

Seven patients with hydrarthrosis affecting one or more joints were studied. 5 had typical rheumatoid arthritis and 2 an atypical disease which was probably also rheumatoid arthritis. In only 1 case was the joint severely inflamed. Four of these patients received 25,000 units of penicillin in 25 ml. of normal saline solution administered intramuscularly every 3 hours and 3 received 40,000 units. In each instance samples of serum and joint fluid were obtained simultaneously $\frac{1}{4}$, 1, 2 and 3 hours after the

patient had received the eighth dose of penicillin. In 4 instances, however the samples were obtained 3 hours after the sixteenth dose, and in 1 instance, material was obtained 3 hours after the twenty-fourth dose. The concentrations of penicillin in both the blood sera and the joint fluids from these patients were determined by the cup assay method as modified by Cholden (*J. Biol. Chem.*, 1944 47 402).

In all cases penicillin was found to penetrate readily into the joint which resulted in that essentially equal amounts of the penicillin entered the joint fluid and blood serum 1 hour after its administration. In the case of the serum concentrations, it is true, they fell rapidly after 1 hour and at the end of 3 hours little or no penicillin was detectable in this body fluid, however in the joint fluids the concentration of penicillin decreased more slowly there being appreciable amounts of penicillin present 3 hours after its administration.

According to Rammelkamp and Keefer the effective concentration of penicillin in the blood is 0.3 Florey unit per milliliter and in the serum, 0.56 Florey unit. The joint fluid of the cases studied 1 hour after the administration of penicillin showed amounts of penicillin varying from 0.15 to 0.24 unit per milliliter and the determinations made 3 hours after administration in 6 of the 7 patients showed that it still contained from 0.05 to 0.17.

The authors conclude, therefore, that the amounts of penicillin which are antibacterial for the common pathogens invading joints are obtained in the synovial fluid by the intramuscular administration of penicillin in the doses discussed.

Penicillin did not tend to accumulate in the joint fluid.

JOHN W. BARNHART, M.D.

Bevans, M.: Changes in the Musculature of the Gastrointestinal Tract and in the Myocardium in Progressive Muscular Dystrophy. *Arch. Path., Chic.* 1945 40 225.

In this article 4 cases of progressive muscular dystrophy are reviewed, with special reference to lesions in the myocardium and in the smooth muscles of the gastrointestinal tract. Progressive muscular dystrophy has been regarded as an intrinsic disease of the muscles. More recently the disease has been classified as a disorder of the autonomic nervous system.

In the past many workers have found diffuse scarring and deposits of fat in the myocardium of patients afflicted with progressive muscular dystrophy. Many others denied having found any pathological changes in the myocardium or gastrointestinal tract in these cases. Other investigators described a cardiointestinal syndrome in patients with progressive muscular dystrophy which was accompanied by vomiting, generalized abdominal tenderness and pain, diarrhea, tachycardia, and signs of cardiac failure. One author found recent genitological changes in the esophagus similar to those described in scleroderma.

A detailed account of the history, physical findings, the course in the hospital, laboratory data and autopsy findings is given of the 4 patients with progressive muscular dystrophy. All of them died of pulmonary complications. The disease was usually discovered at the age of 4. It terminated with the death of the patient from 10 to 16 years later. The treatment of most of these patients consisted of the administration of acetylcholine, aminoacetic acid, vitamins B and C, and other purely supportive symptomatic measures.

All of these patients showed considerable wasting of all of the skeletal muscles on admission to the hospital. No muscular fibrillation was observed. Contracture of the muscles, especially of the plantar aponeurosis, gastrocnemius, and hamstrings was seen which placed the lower extremities in a froglike position. Abnormally increased mobility of the shoulder, hip and small joints of the hands was found. In most cases reflexes were absent. The electrocardiogram showed a right axis deviation and tachycardia in a few of the patients. The roentgenograms revealed moderate decalcification and considerable underdevelopment of the bones. In some instances the esophagus was slightly displaced by a dilated right auricle.

The laboratory data were normal except for a somewhat lowered basal metabolic rate in some cases.

On the autopsy table the muscles were found to be pale, thin, and streaked with yellowish fat tissue. In most cases the gastrocnemius, recti pectoral, iliopsoas and intercostal muscles were most seriously affected in the order mentioned. The heart was found to be hypertrophied and the endocardium was

thickened and streaked with fibrous bands. Some sections of the myocardium and papillary muscles were found to be completely replaced by scar tissue.

Microscopic examination of the skeletal muscles showed changes usually found in progressive muscular dystrophy. Large channel-like structures showing disintegrated muscle fibers in their lumens and capillaries in their walls were very significant. Such structures probably represent the persisting perimysium after the muscle fibers have disintegrated. Other findings were great variation of the size and shape of the fibers, vacuolation and clumping of the sarcoplasm and proliferation of the nuclei of the sarcolemma.

Sections of the myocardium and papillary muscles showed hyalinization, fibrosis, interstitial hemorrhages surrounded by mononuclear cells with phagocytosed red blood cells. The lower part of the esophagus showed considerable edema of the lamina propria, and the epithelium was irregularly desquamated. The small intestine showed similar changes in the muscular layers. In spite of the edema the width of the walls was greatly reduced and the muscular layers were atrophied. The rectal mucosa exhibited infiltration of red blood cells and areas of autolyzed mucosa. The muscularis mucosa layers were fragmented. The longitudinal and circular layers were atrophied and the muscular fibers widely separated.

No lesions of the smooth muscles of the vascular system or of any other organs were noted. With the exception of the presence of thymic tissue in 1 case no abnormalities of the endocrine glands were observed.

GEORGE L. REIS, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Gurdjian, E. S., and Walker, L. W.: Traumatic Vasospastic Disease. *J Am Med Ass* 945 129 668.

It has been known for some time that workers exposed to repeated percussion may develop circulatory disturbances in the hands. The condition is most frequently associated with the use of the pneumatic hammer or jack hammer. Pneumatic hammer disease has become synonymous with white fingers, dead fingers, traumatic vasospastic syndrome, vasospastic disease of the hands, and Raynaud's disease.

The first report on pneumatic hammer disease was made by Longa of Rome in 1911 while the first report on this condition in this country was made by Cottingham in 1917. Hamilton described the clinical findings in detail in 1918 after studying the problem arising out of a dispute between Indiana limestone cutters and their employers over the use of the pneumatic chisel.

The clinical pattern of traumatic vasospastic disease of the hands is almost stereotyped. After a few months to several years of exposure to the vibrations the patient notices attacks of blanching and numbness of the fingers. The pallor is much more pronounced than in Raynaud's syncope but it is not succeeded by the stage of extreme asphyxia so characteristic of the latter. It is not symmetrical even when in both hands.

The attacks may occur while the patient is working. Usually the blanching is most pronounced early in the morning particularly in cold weather. The attacks can be brought on by washing the hands in cold water or by going outdoors for a while in cold weather. They usually come on more frequently in the winter months, when exposure to cold is more apt to occur. Emotion does not appear to produce the attacks. The attacks do not result in wasting and death of the tissue. The workers are also subject to Raynaud's and Buerger's diseases and hemiparathesias not caused by the vibrations.

The present study is concerned with the clinical findings and the microscopic findings in the capillaries and arterioles of the fingers in 6 women war workers using a pneumatic riveter in airplane construction work in Detroit. The authors do not state the percentage of women affected in this occupational classification but to their knowledge this condition has not been described in women previously. Microscopic studies of the finger tips have not previously been reported. Serial sections of biopsies of the finger tips of 5 of the 6 patients showed no pathological changes except in two sections, revealing a red staining amorphous substance in the capillary.

The mechanism of the disorder is as yet unexplained. The possibilities mentioned are low tem-

perature of the surrounding air at the place of work, anemia of the hand from holding the air hammer too tightly and injury to the myoneural junctions of the arterioles in the fingers.

The clinical course of these patients has been characterized by attacks of benign vasospasm with little increase in severity over a period of 3½ years of study. The discontinuance of the use of the pneumatic hammer has not resulted in a single case of relief.

In the discussion de Takats stated that he believed that tools having a high vibration rate may produce a percussion neuritis. He mentioned Deny Brown's experiments with a single percussion of a nerve trunk which indicate that the damaged myelin escapes from its sheath into the endoneurial space and sets up an irritative internal demyelination of a mixed nerve which results in causalgia with its inco-ordination of circulation.

JOHN E. KIRK-UTRICE, M.D.

Elkin, D. C., and Kelly, R. P.: Arteriovenous Aneurysm. *Ann. Surg.* 1945, 33 329.

A near disaster from hemorrhage from the posterior tibial vessels in the course of the excision of an arteriovenous aneurysm prompted the authors to modify their approach to these vessels and remove the upper portion of the fibula, with resection of the head of that bone when it became necessary. The collateral anastomosis which develops as the result of arteriovenous communication together with dilatation of the vessels, including those which perforate the interosseous membrane demands direct visualization of these vessels and their careful ligation and division. Otherwise the retraction of vascular channels through the interosseous membrane may result in serious or even uncontrollable hemorrhage and necessitate a second incision along the front of the leg or the removal of the fibula in the presence of hemorrhage and at an inopportune time during the course of the operation. While this operation has been performed primarily as an approach to arteriovenous fistulas and aneurysms of the posterior tibial vessels it is of equal importance to realize that the same approach is necessary to reach the anterior tibial and peroneal vessels in the upper part of their course. The authors prefer continuous spinal anesthesia for the procedure.

The operation is described in detail with illustrations of the technique. There are 15 case reports given with the preoperative findings. It is interesting to note that enlargement of the heart is not present in all cases, but it is found in some of them and seems to depend upon the length of time from the injury to the examination made before surgery.

The authors' conclusions are as follows:
Careful exposure of the tibial and peroneal vessels in the upper part of their course is necessary in the

INTERNATIONAL ABSTRACT OF SURGERY

made it possible to observe the mechanism of flow, turbulence, and the effect of constriction. The axial and peripheral phases of flow could be observed. If a thread introduced into the lumen was small enough to remain in the clear peripheral zone, there was little evidence of turbulence. If the thread, because of its size or length, projected into the axial phase, pronounced turbulence would occur. The effect of a venturilike constriction was also studied and it was found that the turbulence produced distal to the constriction was capable of producing a propagating clot. These findings emphasize the observed facts that when good approximation of the vessel without occlusion or distortion of the vessel is obtained with fine close suturing, no intravascular clot will form and the anastomosis will be successful.

Types of suture material. No catgut of a size comparable to No. 000000 silk is obtainable, and no actual anastomosis of arteries is obtainable, and no catgut ligation tends to produce thrombus formation and intravascular clotting to a greater extent than does ligation with silk. It would appear that catgut would not be a suitable material even if it existed in the necessarily small sizes.

It is emphasized that even though thrombosis may occur postoperatively the process is a slow one which admits of the establishment of an adequate collateral circulation so that the end result physiologically may be the same as though perfect technical results had been obtained. There are only a few technical fundamentals which must be adhered to: (1) use fine arterial needles and silk (No. 000000); (2) keep the suture gap less than 1 mm. (3) approximate the ends accurately; (4) use anticoagulants freely but judiciously; and (5) use mechanical aids, such as the soluble rod technique, when possible.

BLOOD TRANSFUSION

Neefe, J. R., Stokes, J., Jr., and Gellis, S. S.: Homologous Serum Hepatitis and Infectious (Epidemic) Hepatitis. Experimental Study of Immunity and Cross Immunity in Volunteers. A Preliminary Report. *Am J Med Sci* 935: 210, 561.

Homologous serum hepatitis and infectious epidemic hepatitis have several characteristics in common. Both etiologic agents pass through bacterial filters and are not destroyed by heat at 56° C for 30 minutes. Both also produce similar clinical manifestations. However with infectious hepatitis the transmission is common, the causative agent being found in the feces. Epidemic hepatitis may be prevented or attenuated by means of human immune serum, globulin, or human adult plasma. The presence or absence of cross immunity between the two diseases has not been established. Six human volunteers recovered from homologous serum hepatitis and failed to develop any acute clinical manifesta-

tions upon reinoculation of the causative agent of this disease whereas 8 of 9 normal controls developed hepatitis and jaundice. The 6 volunteers were also inoculated with material containing the etiologic agent of epidemic hepatitis and as a result 5 again developed hepatitis. Controls inoculated orally contracted epidemic hepatitis, but the controls which were inoculated parentally did not develop to the disease. The incubation period of serum hepatitis exceeded 60 days, whereas that of infectious hepatitis did not exceed 37 days.

The authors believed that the lack of cross immunity between the two diseases was due to differences in the antigenic properties of the two etiologic agents, which they believe were not identical. In the addendum, it was noted that recently 8 volunteers were found to be resistant to reinfection by the agent of infectious hepatitis for a period of 8 months after recovery from this same disease.

BENJAMIN G. P. SEATON, M.D.

LYMPH GLANDS AND LYMPHATIC VESSELS

Loeake, L., and Craver, L. F.: The Diagnosis of Hodgkin's Disease by Aspiration Biopsy. *Blood J News* 1948: 75.

Biopsy by means of aspiration through a needle has become an indispensable method of obtaining tissue for microscopic diagnosis at the Memorial Hospital, New York. The technique is now well established and the method has been repeatedly described. The authors between, report in detail the steps of aspiration biopsy according to their technique. They state that naturally first care must be used (1) in accurate localization of the tumor by means of straight posteroanterior and straight lateral roentgen films (2) in fluoroscopic check of the position of the point of the needle (3) in avoidance of trauma to the lung (4) in avoidance of any reflux or injection of tumor material or air into the lung or into a blood vessel and (5) in keeping the patient horizontal during the procedure, and very quiet for some hours afterward. Currently, a considerably greater number of intrapulmonary malignant tumors are yielding microscopic diagnoses as a result of aspiration biopsy rather than as a result of bronchoscopic biopsy although the latter procedure is always given precedence unless it would obviously be useless.

Among 243 cases of histologically proved Hodgkin's disease treated at Memorial Hospital for the most part within the past 5 years, the diagnosis was established by open biopsy in 228, while aspiration biopsy yielded a reliable diagnosis in 14 cases. In the 14 cases of Hodgkin's disease in which the diagnosis was made by examination of the sectioned clot obtained by aspiration biopsy the material was from the lymph nodes in 9 cases, from a prestenal node in 1 case, from the lung in 3 cases and from the spleen in 1 case.

Among the 228 cases in which formal biopsy was used to prove the diagnosis aspiration biopsy had

been previously attempted but had been unsuccessful in 11 cases. Thus in 25 cases of the total number of 232 aspiration biopsy had been selected as the first method on trial for good reason and was diagnostically successful in 56 per cent of the group.

The authors conclude that in cases of Hodgkin's disease without enlarged peripheral lymph nodes yet with nodes or masses accessible to needle puncture the method of aspiration biopsy has often proved successful in establishing the diagnosis. Success depends in large measure on examination of a sectioned blood clot from the aspirated tissue by an experienced pathologist.

HERBERT F. THURSTON, M.D.

MISCELLANEOUS

Sarmiento P. B.: Some Consideration Concerning the Surgical Treatment of Elephantiasis of the Extremities (*Algunas consideraciones sobre el tratamiento quirúrgico de la elefantiasis de los miembros*). *Rev. esp. cir. traumat. ortop.* 1945 3: 145

The majority of authors agree that a primary infection of the lymphatics predisposes to a septic infection which in extreme cases may lead to elephantiasis. The condition is characterized by an exudate rich in leucocytes, fibrous hyperplasia and thrombosis and obliteration of the blood vessels in the subcutaneous tissues. In many instances no streptococci or parasites can be found and a special susceptibility of the lymphatic or lymphovenous system must be assumed. The causes of such abnormal conditions of the lymphatics may be of a local or general character.

As to the treatment of the condition Cornachan suggested ligation of the main artery but the resulting necrosis soon discredited this operation. Winthorpe recommended a gradual compression of the main arteries but the same objection may be raised to this procedure as to ligation of the main artery. Buchman suggested ligation of the main vein of the involved extremity while Leriche recommended a periaxillary sympathectomy basing his recommen-

dation on the hypothesis of the existence of sympathetic fibers in the lymph vessel walls. Rogers advocates extensive removal of the involved tissues and insists upon the necessity of repeated interventions. Hanley described a procedure which he calls "lymphangioplasty," consisting of the introduction of silk fibers into the affected zone and extending them into normal regions. In this manner he expected to establish artificial capillary drainage from the involved to the healthy tissues. Le Dantec supplemented Hanley's procedure by immunization with a certain vaccine. Walther buries rubber tubing in the involved tissues while Lanz extirpates extensive portions of the tissues and introduces fascial strips in order to establish drainage. Kondoleon suggested an extirpation of the aponeurosis in order to facilitate deep drainage. Payr and Oppel described similar methods. Castellani advocates daily injections of fibrinolytic or acetosalicylic thiosinamine. Mata recommends the administration of streptococcus vaccine before any operative intervention.

The author operated on a 39 year old woman who developed a suppurative process in both inguinal regions at the age of 15 years. Following these lesions a tremendous elephantiasis of both lower extremities gradually developed. The author believes that repeated infections in the form of dermatitis, probably of a streptococcal origin led to an infection of the lymph glands and lowered the resistance of the skin. Apparently repeated dermatitis with resulting lymphangitis produced cutaneous alterations and changes in the lymph vessels.

As to the treatment the author employed a procedure consisting of resection of a large amount of tissue. He followed Sistrunk's technique modified by Kondoleon. In extensive cases of elephantiasis the operation must be performed in stages.

The author resected 9.5 kgm. of tissue under spinal anesthesia from the left extremity and a similar amount from the right extremity. Catgut No. 0 was used for ligatures and the tissues were approximated with catgut No. 3. A check-up 8 months later showed very satisfactory results.

JOSEPH K. NARAT, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Ivancov, C., Jr.: *The Hypochloremic State in Surgical Patients*. Surgery 1945 18 535

Four cases are presented which illustrate an exception to the rule of withholding salt administration postoperatively. These cases are examples of severe hypochloremia following extensive burns, persistent vomiting from pyloric carcinoma, chronic high intestinal obstruction, and biliary obstruction, respectively.

The condition of hypochloremia is equivalent to heat exhaustion passing into the subacute or chronic phase due to persistence of the chloride loss. Clinical recognition of the hypochloremic state is difficult because of its rarity and the bizarre clinical picture it presents. The conditions most commonly associated with the loss of large quantities of electrolytes are gastrointestinal drainage, pyloric obstruction with vomiting, persistent external biliary fistula, high intestinal fistula, extensive granulating surfaces, persistent fever and excessive sweating from a long operation during sultry weather.

The clinical manifestations of the hypochloremic state may be classified as either prodromal or advanced. The advanced symptoms are acute and prostration. They are usually characterized by a blood pressure of 80 or below, and a soft, easily compressible pulse which is almost unobtainable. The skin is cold and clammy and excessive thirst is accompanied by extreme weakness and prostration is common.

The acute advanced symptoms may be preceded for several days by the prodromal symptoms which consist of mild cramplike persistent abdominal pain, nausea, moderate abdominal distention, and repeated vomiting of small amounts of bile stained fluid. The patient may appear languid or drowsy and may develop an intractable hiccough. Anorexia is almost always present, and bowel movements and flatus are absent. Oliguria and uremic symptoms are fairly constant. The clinical similarity of the hypochloremic state to the picture presented by salt intoxication—the acute abdomen, postoperative ileus and intestinal obstruction due to nutritional edema—makes it extremely difficult to differentiate these conditions, except for the finding of a low blood chloride in the clinical conditions mentioned.

The importance of early diagnosis of the hypochloremic state is apparent, since the condition may rapidly progress to fatality from an extreme shock like state with uncompensated alkalosis and extrarenal azotemia. Active therapy consists of massive fluid and salt administration preferably by the

intravenous route. Shock due to the acute hypochloremic state will not respond to the usual administration of blood plasma, and non-specific intravenous fluids. The Collier clinical rule for salt replacement and daily blood chloride determinations are accurate guides to treatment.

JOHN L. LINDQUIST, M.D.

Starr, L., and Mayrock, R. L.: *Convalescence from Surgical Procedures. Studies of the Circulation Lying and Standing, of Tremor and of a Program of Bed Exercises and Early Rising*. Am J Surg 1945 10 701

The purpose of the authors' investigation was to search for objective abnormalities during convalescence from surgical procedures by a available special techniques and by other methods which might be devised. If one could discover objective abnormalities they might be used as a test for the duration of convalescence and also as a means of judging the success or failure of attempts to shorten the convalescence which was also part of the authors' project. In planning the work the authors expected that few abnormalities would be found when convalescent subjects were studied at rest, but when they were asked to perform tasks, it was expected that abnormalities would be discovered. For such tests, tasks that the patients were accustomed to were preferred. The first test consisted of observing the changes in the circulation which took place on arising, the second of studying the effects of mild exercise, that of pushing up and lowering a weight. The results of the latter are reported elsewhere.

Forty-four patients were studied before and repeatedly after surgical operations. The test used consisted of estimates of the pulse rate, blood pressure, and cardiac output (ballistocardiogram) under standard conditions in both the horizontal and vertical positions.

The average of the results obtained in 25 cases operated upon for hernia disclosed that the following significant changes occurred during postoperative convalescence:

In the horizontal position the cardiac output was diminished soon after operation, and the blood pressure was diminished later. In the vertical position the pulse rate was increased, the cardiac output tended to be increased and the systolic blood pressure tended to be diminished.

The difference between the lying and standing pulse rates increased, and the ratio between the lying and standing cardiac outputs was changed after operation. There was more tremor after operation. The subjects were unable to remain standing after operation.

After more serious operations the changes found in convalescence were generally similar to those described after herniorrhaphy with two exceptions

(1) the administration of large amounts of fluid by vein prevented the postoperative fall of the cardiac output or caused it to increase, and (2) when the operation permitted better nutrition of the patient improvement from this cause far overbalanced the effects of the operation per se.

JOSEPH K. NARAT, M.D.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Lalich J. J., and Mason J. M., III: Resuscitation of Severely Wounded Casualties. *Surgery* 1945 18 747

During the North African and Tunisian campaigns and the Anzio-Nettuno beachhead operation in Italy a great number of severely wounded casualties were observed. Many men came into the receiving tent with a blood pressure of 0/0. Their condition was judged by the manner in which they responded to transfusions of plasma and whole blood. It was believed that in cases in which the systolic pressure rose to 80 mm. of mercury and remained at that level the chances that the individual could undergo a major operation would be quite satisfactory. However in cases in which there were compound head injuries, penetrating wounds of the chest or abdomen, or compound injuries of the femur it was more difficult to get the casualties prepared for surgery. It was felt that plasma or blood could be given fairly rapidly. When the desired systolic pressure was not maintained reasonably, the patient was given a high priority for surgery. Hemorrhage was the greatest cause of a drop in the blood pressure in this group. Infection and cardiorespiratory embarrassment must be combated intelligently in association with severely wounded casualties. If and when the systolic pressure dropped in the preoperative and surgical phases of treatment, during the time blood or plasma was being injected the drop in pressure was combated by increasing the amount and rapidity of the infusion.

When the systolic pressure reaches 100 mm. the patient should be given an additional 500 to 1,000 c.c. of blood, either preoperatively or during surgery before resuscitation is considered adequate.

Three cases are reported in detail to illustrate the points brought out.

RICHARD J. BERNETT, JR., M.D.

Rawles, B. W.: A Routine for Early Skin Grafting of Deep Burns. *Surgery* 1945 18 696

This article presents the experience in the treatment of a group of 154 patients with burns in an overseas U.S. Army General Hospital in Italy during a period of 14 months. Forty-two or 27.3 per cent of the burn cases, required grafting as compared with 54 per cent of a group of 78 burn injuries previously reported the great difference being due to the position occupied by the hospital in the chain of evacuation during the two periods. In a number of instances the burns were associated with injuries

of the nerve bone and soft parts since 33 per cent of the patients had been wounded in action. The author's study deals primarily with the late management of deep burns since a majority of this group received the initial treatment in other medical installations and were transferred to this hospital from a few days to several weeks after the injury.

The control of infection is of paramount importance at this time if prompt healing with early and successful grafting when indicated is to be accomplished. Infection besides jeopardizing the life of the patient complicates the successful treatment of burns in the following ways: (1) the healing of second degree burns is delayed; (2) deep second degree burns with sufficient viable epithelium for complete coverage may be converted into third degree burns; (3) in third degree burns deeper destruction of tissue occurs with an increase in scar tissue formation; (4) grafting may have to be delayed unnecessarily and may even be unsuccessful and if so is followed by the formation of more scar tissue and contractures; and (5) even after the successful take of grafts, furuncles and pustular infection delay the healing of small uncovered inbetween areas and destroy portions of viable grafts days or weeks later. The problem therefore in burn therapy after shock has been overcome is to control infection and obtain a closed wound as rapidly as possible either by the healing of undestroyed epithelium or by skin grafting.

Penicillin is used in the primary treatment of burns and is given intramuscularly in doses of 25,000 units every 3 hours. Infection is controlled in the majority of cases, provided the primary dressing is left undisturbed for from 12 to 14 days. It is the author's impression that oral sulfadiazine is just as dependable as penicillin during this stage of the treatment. Any drug therapy is only an adjunct to good surgical management (originally described by Allen and Koch) and briefly consists of (1) meticulous cleansing of the burned surface and (2) a resilient pressure dressing with fine mesh grease gauze next to the burned surface. This should not be changed for from 12 to 14 days. Care is taken to splint adjacent joints and in the case of the extremities, to see that the pressure dressings begin at the toes or finger tips and extend well above the burned area. Elevation of temperature occurs when this routine is used but only on rare occasions is it necessary to change the primary dressing any earlier than 12 to 14 days for the purpose of inspection. All dressings are done in the operating room under strict surgical technique and if the burns are at all extensive, with the aid of an anesthetic. A majority of second degree burns are found healed when the primary dressing is removed and there is only minimal contamination or infection in the case of deep burns. All loose, dead skin and the tops of unbroken blisters are removed in unhealed second degree burns, and a second petrolatum gauze dressing is applied and left undisturbed for another period of 10 to 14 days. Healing is complete in the majority of the remaining patients when the second dressing

INTERNATIONAL ABSTRACT OF SURGERY

is removed, except when there are areas of full skin destruction present which had not been previously recognized.

The recognition of full thickness burned skin and its prompt removal is necessary if grafting is to be done early. The identification of nonviable skin by means of sodium fluorescein and the excision of such areas, followed by immediate grafting when the burn is first seen or at the time the first or second dressing is done, has been suggested. The practice is to excise all or as much demarcated slough as possible at the time of the first change of dressing and thereafter at intervals of 3 or 4 days until all of it is removed.

In the author's experience moisture often seemed to enhance the growth of bacillus pyocyaneus, and to surrounding skin edges. In June, 1944, at the suggestion of Lyons, he began applying dry fine mesh gauze pressure dressings after the last slough had been removed, and continued or began giving penicillin intramuscularly in doses of 25,000 units every 3 hours. The dressing is left undisturbed until the patient is taken to the operating room 4 to 6 days later for grafting. The additional time is used to bring the blood values to normal with transfusions of blood or plasma, as indicated.

The following advantages result from this routine. First, infection is controlled, second, grafting is more successful since infection is controlled and also because this routine makes earlier grafting possible. Third, the patient's discomfort is greatly reduced by this simple routine. Fourth, scar tissue and resulting contractures are diminished by early grafting. Fifth, the amount of dressings, drugs, and other supplies necessary for treating a burn is reduced, medical personnel are freed for other duties, and many days of hospitalization are saved.

When this technique is used the burn wounds are found covered with healthy granulations at the time of grafting, although 4 or 5 days previously the action was carried down to subcutaneous tissue. These granulations are not disturbed. However in the patients admitted late, it is often necessary to cut the exuberant granulation away. Split-skin grafts are always used, and are removed either with the Padgett dermatome or with a modification of the Blair Brown knife in place except in the case of large grafts where a roller attachment. Grafts are not sutured in place except in the case of large grafts to the original size (to do so if the stretch of the skin to the original size is to be obtained). It is the experience of the author that grafts become firmly adherent within a few minutes after being placed, because the necessary substances for adherence are present in the wound itself.

Furuncles and postural infection is and about the grafted area can often be a problem. A wet dressing spreads the infection, macerates the skin, and many times leads to pyocyaneus and proteus contamination. All of this delays the healing-over of small inbetween areas or uncovered edges which are sometimes present when an extensive area must be

grafted. In the author's experience, penicillin given periteneally does not control such infection when petrolatum gauze or wet dressings (with saline solution) are used. In fact, oral sulfadiazine seems to be more effective under these conditions. Recently however penicillin dressings have been used on the grafted area after the initial change of dressing when there has been much infection present. Strips of fine mesh gauze are wet with a solution of 350 units of penicillin to each cubic centimeter of normal saline solution and placed over the grafted wound. This is sealed over with petrolatum gauze to prevent too rapid absorption of the solution by the overlying dry dressing, and is changed once daily until the infection is controlled. This seems like a paradox since infrequent change of dressings during the acute stage of the burn, and previous to grafting is stressed as being very necessary if infection is to be controlled. When dressings are not changed for 3 or 4 days, destruction of previously viable grafts results from the accumulation of pus, if pustules or furuncles are present in the grafted area. Furuncles and postural infection after grafting were reduced by the use of penicillin dressings.

John E. KEMPENACK, M.D.
Rubin, L. R.: Contiguous Skin Flaps for Wounds of the Extremities. *Am. J. Surg.* 1944, 7, 34.

Closure of avulsed wounds in which the loss of skin and deep tissue is extensive may be effected by the use of tube and flap grafts, or by means of contiguous skin flaps. The author attempts to summarize, with the aid of drawings, photographs, and charts, his experience with 50 selected war wounds of the extremities closed by the various contiguous skin flap techniques.

The skin adjacent or contiguous to a wound is mobilized by the use of planned incisions which permit the contiguous skin to cover the defect after advancement, rotation, or transposition of the skin flap. Often extensive undermining opens large areas of these to bacterial invasion, but chemotherapy particularly with penicillin, reduces this hazard. The author has also made use of multiple transpositions, where indicated, to aid wound healing.

This technique is applicable to wounds requiring new skin tissue which (1) will cover exposed bone, tendon, or deep irregular muscle defects, (2) will not adhere to underlying muscle when fascia is missing, and (3) will not contract. However it is pointed out that skin manipulation beyond a certain point will compromise the blood supply as to limit the use of the flaps must contain all layers (fat down to the deep fascia). The flaps are most successful where the skin is lax, as on the abdomen, back, and face. Only clinical judgment determines the limits of undermining for safe closure.

Buried absorbable sutures along with plaster of Paris splints are used to relieve the tension at the edges of a wound. Planned incisions are made along Langer's lines, and irregular wounds are transformed

into geometric designs (triangles and rectangles). Closures are effected to give figures H, Y, Z, T etc. Wherever the position of the flap necessitates cutting across the main sources of blood supply the author employs the technique of "delaying" which uses the principle of a gradual, rather than a sudden reduction of blood supply. The flap after being outlined through the skin, subcutaneous tissue and fat, is completely lifted from its bed, only to be replaced immediately and resutured in its former position until the blood supply at the base becomes adequate. This may require multiple stage operations.

Local anesthesia, even without adrenalin should never be used. The injected fluid acts as a mechanical barrier to capillary circulation and of course adrenalin is contraindicated because of its vasoconstricting action. Brachial block for the arms and spinal anesthesia for the lower extremities are recommended. For individuals with a high vascular tone, who are sensitive to the vasoconstrictive effects of cold, pain, and trauma use is made of lumbar paravertebral block (below) and stellate block (above).

Direct heat to an ischemic area favors necrosis because the local metabolic needs are more greatly increased than is the blood supply. Nevertheless, heat applied to the trunk of the body is beneficial by virtue of reflex vasodilatation in the extremities without an elevation of the local metabolic needs.

In instances of associated nerve injury it may be best to use a split skin cover immediately and to defer the flap closure until the nerve has been repaired.

The contiguous skin flap is designed primarily for utility and no attempt is made to obtain a cosmetic result.

DAVID H. LYNN, M.D.

Newman, P. H.: Early Treatment of Wounds of the Knee Joint. *Lancet* Lond., 1945 249 632.

This article deals with the treatment of wounds of the knee joint. The author classifies these wounds as slight, moderate, and severe, of which there were 10, 39, and 8 respectively. He discusses the diagnosis of the type of joint injury and the treatment.

In the first group aspiration, intra-articular penicillin, and immobilization by means of a plaster cast was found sufficient. In the second group careful wound incision, primary suture, intra-articular and parenteral administration of penicillin with immobilization and extension in the Thomas splint were instituted. Among the 49 cases in these two groups there was only 1 case which gave him much difficulty.

In the remaining 8 cases falling in the "severe" classification because of the time element and contamination 5 of the wounds were left open. The other 3 were closed and treated the same as those in the first 3 groups.

Foreign bodies were removed at the first operation whenever this procedure was reasonable and possible. A separate incision was found to be necessary in a few cases. The importance of preoperative

roentgenographic films was stressed. The author also calls attention to the fact that nonradiopaque foreign bodies such as wood and glass may be a source of trouble. Frequently the history of the accident will put the surgeon on his guard in the last type of case.

PAUL MERRILL, M.D.

Caldwell, G. A.: Secondary Infection of Wounds. *Ann. Surg.*, 1945 122 645.

Secondary infection following the original infection of an open wound is so commonplace as to pass unnoticed. The average surgeon accepts it as a matter of course and unless the patient's life is endangered or his leg is about to require immediate amputation he thinks nothing need be done to improve the situation. Actually secondary wound infection is the principal cause of delayed healing and impaired function. Moreover such infections are to a great extent preventable and even established infections can frequently be eliminated.

Primary wound infections (to distinguish them from the secondary) are those caused by bacterial contamination at the time of injury. These bacteria are derived from soil, clothing, skin and foreign bodies.

Secondary infections are those caused by bacteria introduced into the wound at any time after the initial injury. These invaders may come from the skin of anyone touching the wound from unsterile instruments or dressings, or from the respiratory tract of the patient or of his attendants. They may fall into the wound with dust from the floor of a ward and may be drawn by capillary attraction through a soggy dressing which is in contact with soiled linen.

Only 5 per cent of fresh wounds were found to be infected with hemolytic streptococci and staphylococci and bacillus pyocyaneus upon admission to the hospital, but after a week in the institution 50 per cent of the wounds contained secondary invaders and later on they were found in from 70 to 80 per cent of the open wounds.

Pathogenic organisms can be eliminated in most cases by the body's defense mechanisms when these are aided by adequate surgical débridement. They persist as serious or trivial infections in from 10 to 25 per cent of cases. They appear as new invaders and produce serious and trivial infections in from 20 to 50 per cent of cases. Of the serious persistent infections developing in wounds probably at least half are caused by bacteria secondarily introduced.

In view of these facts the "laissez faire" attitude of surgeons toward secondary wound infections is not justifiable. Surgeons are correct in placing more emphasis upon the general condition of the patient and adequate drainage but are incorrect when they ignore the changing bacterial flora in the wound under treatment.

Detailed modes of treatment including meticulous operative technique supplemented by the administration of sulfonamides or penicillin before and after operation are described and illustrated by cases.

HARRY W. FINE, M.D.

INTERNATIONAL ABSTRACT OF SURGERY

Birks, P. A.: Infections of the Superficial Palmar Space. *Lancet* Lond. 1945 249 669.

The author presents 5 cases to illustrate the effects of incorrect and correct management of infections of the superficial palmar space. These infections have gained little recognition by virtue of their comparative rarity and the ill defined anatomical nature of the space. The space lies in the hand between the palmar fascia and the flexor tendons, proximal to the transverse crease of the palm. It is doubtful if it exists in the normal hand. According to Inell, the boundaries of the superficial pretendinous central palmar space are:

- Anterior the palmar fascia
- Posterior the tendons and lumbrical muscles
- Internal the fourth intermetacarpal space
- External the union of the palmar fascia with the intermuscular aponeurosis of the second metacarpal
- Proximal the union of the palmar fascia and transverse ligament
- Distal the fusion of the middle palmar spongy

Fluid injected just through the palmar fascia mixes freely with fluid injected through the web of the middle finger into the middle palmar space. However indefinite this space may be in the normal hand a collection of pus behaves as though it was confined between tendons and palmar fascia. In the early stage extension of the infection occurs principally through the palmar fascia.

Clinically in from 3 to 10 days after injury the hand becomes painful and the palm swollen especially proximally and a purulent blister collects under the skin. The fingers are semiflexed, active movements are restricted and painful there is little edema of the dorsum but a great general upset. The abscess should be opened before the palmar fascia sloughs (that is, early) under unhurried anesthesia and with a tourniquet. The incision should be over the most prominent part of the swelling and along the line of the crease. The fascia is opened with alnus forceps. The superficial palmar arch under the fascia is pushed out of danger by the pus. Tubercare unnecessary for drainage. The after care consists of

Fig. 1 Longitudinal section through hand (after Cutler 1945) showing anatomical position of the superficial palmar space

immobilization on a wire splint with frequently changed dry dressings.

DAVID H. LYON, M.D.

Pratt, E. L.: Clinical Tetanus. *J Am Med Ass* 1945 129 1243

The classification of 56 children with tetanus in the order of the severity of their infection was of use in evaluating the methods of treatment employed. There was no evidence that amounts up to 80,000 units of tetanus antitoxin was more effective than amounts of 30,000 units. The intrathecal administration of tetanus antitoxin was probably but not definitely more effective than the intramuscular or intravenous administration of the same amount of antitoxin.

Fatal reactions occurred from tetanus antitoxin given intrathecally to some patients, who in all likelihood, would otherwise have survived their tetanus infections. Hence, tetanus antitoxin should not be used intrathecally in any but the most severe cases, if it should be used at all, until a preparation is available which is incapable of producing severe reactions.

Excision of the site of infection, once clinical symptoms of tetanus were present, did not ameliorate the course of the disease.

SIMONE KAHN, M.D.

Noel H. B., and Cole, J. P.: The Bacteriology of War Wounds in the Pacific Area. *U S War Med Bull* 1945 45 1137

A hospital ship in the Pacific area treated 730 fresh battle casualties in a little over one year. Care of all of these wounds was highly desirable, but physically impossible because of the shortness of time, the large number of casualties and the brevity of laboratory personnel. One hundred and sixty-one cases had wound cultures. These were severe wounds caused by shell fragments in 86 patients, bullets in 54, and unknown missiles in 21.

In contrast to civilian wounds, which are usually seen by a surgeon within a few hours these wounds did not receive treatment for from 24 to 48 hours because of the ferocity of battle and the difficulties of transportation. Eighty-three patients in this group had their wounds cultured and were under treatment within 24 hours. An additional 30 patients were seen during the second 24 hour period.

Whenever possible, tissue was taken from the wound for culture. When it was not available, swab cultures were made on blood agar and trypticase, a dextrose-agar stab heated at 70°C. for 10 minutes, a meat infusion medium, a dextrose-agar (unheated), and litmus milk were inoculated.

The authors' attention was centered on anaerobic cultures, and 160 wounds were cultured for anaerobic organisms. Of this group 77 (48.1%) were positive. The most frequent anaerobe cultured was the clostridium perfringens, present in 57 of the 77 wounds. Unclassified proteolytic anaerobes were present in 24 cases, and 23 wounds yielded more than one species of anaerobe. Clinical gas gangrene developed in 27 cases (35% of the anaerobically infected wounds) and in 1 case which failed to yield anaerobes on the

admission culture. *Clostridium perfringens* was the offending organism in 26 cases of gas gangrene while the other case was caused by the *clostridium septicum*.

Direct smears from fresh wounds do not provide a reliable picture of the bacterial flora so one must depend on cultures. Early information is essential particularly in the case of anaerobes, in order to institute treatment before the infection gets out of control. The patients whose wounds yielded anaerobes were carefully observed and the earliest signs of clinical infection detected. This information led to early amputation and probably saved the lives of several patients.

Aerobic organisms were cultured from 120 wounds, and in only 14 wounds were the cultures negative. The *staphylococcus albus* was most often found. Wound infections although frequent, usually remained localized. A case report of a serious complicating aerobic infection is presented.

The value of local implantation of sulfanilamide in the effort to prevent and control infection is doubtful. The authors did qualitative chemical tests on serum from the wounds of patients or on macerated tissue removed at débridement and found that sulfa drugs were present in 60.83 per cent of the wounds from which aerobes were cultured and in 57.14 per cent of the wounds from which anaerobes were cultured. Therefore the local use of sulfanilamide certainly is not bacteriocidal. The value of the drug as a bacteriostatic agent is more difficult to evaluate.

The wounds of 2 patients from which the *clostridium perfringens* was cultured were constantly irrigated with azochloramid solution and sulfadiazine was given orally. One patient, in addition received 640,000 units of penicillin. In spite of this regimen for 9 days cultures of these wounds still yielded the *clostridium perfringens*, although neither patient developed gas gangrene. This would stress the fact that chemical sterilization of a wound is practically impossible. ROBERT R. BICKLOW M.D.

Smith Petermen, M. N. Larson C. B., and Cochran W.: Local Chemotherapy with Primary Closure of Septic Wounds by Means of Drainage and Irrigation Cannulae. *J. Bone Surg.* 1945 27: 563

This article deals with a method of treating septic wounds, whereby the largest part of the wound is closed and cannulae are inserted through the superficial structures down to the septic process. Dakin's solution has been used extensively and even now is often substituted temporarily for other chemotherapeutic agents. Silver pectinate solution has been used in a limited number of cases.

Penicillin has been used for the last year. The technique consists of primary closure of the wound around the cannulae, gauze sponges being packed between the skin and the flange. The dressings stabilize the cannulae. A number of cubic centimeters of penicillin are delivered from the supply

bottle into the wound through the inlet cannula. The outlet cannula is left open until the clear fluid appears, then it is clamped off.

Penicillin is delivered into the wound every 4 hours. The strength of the solution is 250 units per cubic centimeter. The period of administration varies from 2 to 4 weeks. Dressings are infrequent. The cannulae are removed under pentothal anesthesia and the soft tissue defects are closed leaving only a small rubber catheter in place for the administration of penicillin for a few more days. Systemic chemotherapy is used in conjunction with the local chemotherapy. The usual dosage is 100,000 units for 24 hours. Four cases are reported.

CASE 1. A boy 13 years of age had recurring osteomyelitis of the left fibula. The suggested technique was followed and the wound healed completely in one month.

CASE 2. A man 24 years of age had recurring symptoms referable to his right ilium. Roentgenograms showed changes characteristic of osteomyelitis. Operation consisted in sequestrectomy, saucerization and insertion of glass cannulae. The wound healed completely in 5 weeks.

CASE 3. A man 38 years of age had rheumatoid arthritis with a rigid spine and fibrous ankylosis of both hips. In 1934 he had had a fasci lata arthroplasty of the left hip with postoperative sepsis which had persisted for a period of 5 years. During a vitallium mold arthroplasty free pus was encountered in the iliac fossa and treated. There has been no recurrence of sepsis for 6 years.

CASE 4. A man 19 years of age had multiple foci of osteomyelitis occurring over a period of 7 years. In July 1944 acute symptoms from a new focus in the mid-shaft of the right femur developed. Operation included saucerization and insertion of a vitallium cannulae with wound closure. Ten months have elapsed since operation and so far there has been no local recurrence of sepsis.

The authors state that this is not a perfected method with 100 per cent cures. There have been cases with local recurrence of sepsis but these have been relatively few.

A number of figures and roentgenograms showing the method in use are included.

RICHARD J. BENNETT, JR. M.D.

Woodward, F. D. and Holt, T.: The Local Use of Penicillin. *J. Am. Med. Ass.* 1945 129: 589

The local use of penicillin has proved helpful in the control of acute and subacute infections of the nose, sinuses, nasopharynx, pharynx and mouth and has been of occasional benefit in certain cases of chronic otitis media. It has also proved beneficial postoperatively in mastoid and sinus surgery.

It has been of no value in the treatment of acute otitis media, and of negligible or no value in chronic sinusitis and chronic sinusitis associated with allergic rhinitis.

Its usefulness in the treatment of the common cold is still undetermined.

INTERNATIONAL ABSTRACT OF SURGERY

In those cases in which the local use of penicillin has proved beneficial, its effect will no doubt be enhanced by its combined use systematically or by the combined use of an appropriate sulfonamide.

The local application of penicillin does not produce any dramatic change in the bacterial flora present in the nose and throat. Its effect seems to be more bacteriostatic in nature than bactericidal. In the cases of several patients who had recently recovered from scarlet fever the authors were unable to alter the bacterial flora on repeated cultures after local treatment.

The solution 500 units per cubic centimeter and lozenge provide the simplest and most effective means of application. The water-soluble jelly was useful at times for instillation into the nose at bed time and in the treatment of atrophic rhinitis in which the nasal symptoms were ameliorated.

The authors are hopeful that new antibiotics will soon be available, particularly for the gram negative organisms and for the more common bacteria which have become sulfonamide or penicillin resistant.

JOHN J. MACINTYRE, M.D.

Romanaky, M. J., and Ritzman, G. E.: Penicillin Blood Levels for 24 Hours following a Single Intramuscular Injection of Calcium Penicillin in Beeswax and Peanut Oil. *N. England J. M.* 1945 233 377

A single injection of 500,000 Oxford units of calcium penicillin in 4.5 per cent beeswax (by weight) in peanut oil contained in 1 cc. produces and maintains effective levels of penicillin in the blood for about 24 hours and continues to be excreted in the urine for approximately 3 days.

Calcium penicillin in beeswax and peanut oil maintains its potency for at least 6 months at refrigerator and room temperatures up to 37° C. In addition there is no deterioration after 24 hours at 50° C or after two hours at 100° C.

BENJAMIN GOLDMAN, M.D.

Romana, F. E., Jacobsen, L. Y., and Smith, E. L.: Reactions to Penicillin. *Bull. U. S. Army Med. Dep.* 1945 4 694.

The authors study deals with the serious and unusual reactions observed in some 3,000 soldiers receiving prolonged courses of penicillin. In about 0.5 per cent of this group, the reactions were so severe that the penicillin was discontinued. The reactions are classified as follows: (1) urticaria, (2) convulsions, and (3) angioneurotic edema. (4) a syndrome similar to serum sickness, (5) acute syncope, (6) transient miliarialike eruptions, (7) erythematous eruptions, at times simulating dermatophytosis, (8) erythema nodosum and (9) epiglottitis.

The reactions to penicillin have been of two main types—those appearing shortly after first exposure to the drug, and those occurring at a later date as a result of developing sensitization. Those in the first

group are due to pre-existing hypersensitivity to penicillin which may be inherent or may occur as a result of a previous fungus disease. Those in the second group may occur later in the first course of treatment, shortly after its termination, or at various times during subsequent courses. The reactions in this group are indicative of a developing sensitization to penicillin. Here again, previous fungus disease may enhance the development of reactivity to penicillin.

Both early and late reactions may be serious in nature and require discontinuation of the therapy. From clinical observations, it appears that the primary vascular tissue in most penicillin reactions is the vascular bed.

Intradermal testing with penicillin has been of limited value as an aid in diagnosis or guide for further treatment. Increased reactivity to penicillin may occur on the basis of a previous acute fungus disease.

The presence of negative intradermal tests during and subsequent to some of the more serious reactions indicates that clinical judgment in each case is more important than the information obtained from skin testing.

JOSEPH K. NAKAT, M.D.

ANESTHESIA

Rosenstein, E. A., and Hershberg, S. G.: The Utility of Apomorphine in Clinical Anesthesia. *Anesthesiology* 1945 6 374.

The use of apomorphine as a sedative has been limited and it is the purpose of this report to suggest more extensive use of the depressant properties of this drug for several types of cortical stimulation as seen by the anesthesiologist.

Apomorphine in subemetic doses is a valuable therapeutic aid for such conditions as emergency delirium, acute alcoholic psychoses, or patients with developed or impending delirium tremens, drug addicts, and excitability following the use of bella donna alkaloids.

The hypnotic action of this drug is prompt, dependable and safe. Sedative effects become apparent in a few minutes with the reduction or cessation of agitated muscular movements. The blood pressure, pulse, and respiratory rates are constant with whatever changes may result from the elimination of the state of excitement.

Apomorphine hydrochloride is marketed in tablet form, and is subject to Federal regulation as a narcotic. It is relatively unstable and should be discarded if a greenish tinge is visible when it is diluted. The sedative or hypnotic action of the drug has had little stress in most texts. Present clinical experience shows that subemetic amounts are free from the described hazards of respiratory and circulatory collapse. The drug is readily absorbed from all mucosal surfaces but its action is more certain when given parenterally.

The report is based on more than 500 administrations for the therapy of emergency delirium. It was

also used as premedication for emergency operations complicated by severe excitement and acute alcoholism, delirium tremens and severe agitation accompanying morphia addiction. Another field of usefulness was for the marked muscular and psychic overactivity occasionally seen before operation after the hypodermic injection of scopolamine or atropine.

Six case reports were given in detail illustrating the types of cases which showed response to the drug. It was not given as a substitute for other depressant drugs except in the special circumstances mentioned. Experience with the drug was limited to surgical patients. There were no accidents or untoward effects.

The dose varied from 1 to 2 mgm for the average adult patient. It was dissolved in 10 c.c. of sterile normal saline solution and administered intravenously. It was safe to repeat half the amount if sedation was inadequate after 20 minutes, and the entire initial dose could be repeated should the excitement reoccur after several hours.

The drug was contraindicated when either asphyxia or oxygen want seemed to be the important factor in the excitement or delirium.

MARY KARP M.D.

Koppányi, T: Acetaldehyde a Volatile Anesthetic and Sympathetic Stimulant *Anesthesiology* 1945, 6: 603.

This report concerns the effect of acetaldehyde when administered by inhalation. The product used for the study was freshly distilled from paraldehyde in the presence of sulfuric acid and water and adult dogs were the subjects. An undiluted or 30 per cent aqueous solution of acetaldehyde was applied by means of a cone or towel wrapped around the nostrils and mouth. Anesthesia was established within 5 minutes, the trachea cannulated and the common carotid artery exposed and cannulated for recording the blood pressures.

Recovery usually occurred within an hour and was uneventful. Toxic effects of an overdose included profound cardiac slowing which was in part due to central vagus stimulation and idioventricular rhythm. Conventional resuscitating measures were usually successful in saving the animals.

Preliminary medication of morphine or barbiturates reduced the quantity of acetaldehyde needed for the anesthesia. The rate and depth of respiration were increased and there was a substantial rise of the blood pressure. There were sympathetic stimulating actions of the drug in addition to the central depressant action, for it produced all signs and symptoms of typical thoracolumbar autonomic excitation such as pupillary dilatation, relaxation of the diaphragmatic muscles and dilation of the bronchial musculature.

The drug is a local irritant to the skin and mucous membranes, but this action is less than that of chloroform. Its odor may be made less offensive by the addition of various volatile oils or ammonia

water. Acetaldehyde ammonia is a pressor agent and a general sympathetic stimulant, while acetaldehyde sodium bisulfite is not. The inhalation of concentrated acetaldehyde vapors is likely to produce cardiac, vascular and respiratory toxic effects.

MARY KARP M.D.

Thornton H. L. and Rowbotham S. Anesthesia in a Maxillofacial Surgical Unit with the British Liberation Army *Anesthesiology* 1945 6: 580

This article is based on the problems encountered and the anesthesia method employed on 1,687 patients with maxillofacial injuries as encountered by one maxillofacial unit in England during World War 2. The types of injury usually found were classified into the blow-out injury, the through and through injury to the maxilla with disorganization of the nasal passages, the retained foreign body in the tongue, the brawny neck, edema of the glottis, direct involvement of the glottis and larynx and injury involving soft tissue alone.

The premedication for the average case was omnopon (grain 1/5) and scopolamine (grain 1/150) given subcutaneously 1 hour before or intravenously a few minutes before the operation. The nose was cannulated just prior to the injection of anesthesia and the larynx under direct vision prior to passing a tracheal tube.

Induction presented the greatest problem in this type of anesthesia because of the difficulty of placing a mask on the face. The airway was often obstructed partially or completely and there was a tendency to laryngeal spasm. Anesthesia by inhalation was found difficult and intravenous anesthesia was the obvious alternative. A 1 per cent solution of bromethyl (avertin) in 5 per cent glucose when given intravenously produced rapid anesthesia which was highly satisfactory for intubation. The solution was warmed to blood heat and tested with Congo red before use. No laryngeal spasm or strangling was observed in any of the cases and there was early relaxation of the jaw.

Intubation was safely effected in the early second stage. The dosage infused varied considerably but the average case was intubated on 300 c.c. There was no cause whatsoever for anxiety regarding the safety of the drug in the cases presented, with the exception of 1 case which was reported in detail. Death may have been due to primary heart failure.

For intubation the nasal route was most commonly chosen and the procedure was carried out under direct vision in almost all cases. The endotracheal tubes used were plasticized polyvinyl chloride (portex). The advantages of this type over the standard rubber type were the remarkable durability of the tubes, ease of sterilization, freedom from kinking, reduced irritability to the larynx which permitted the lightest possible anesthesia and the unusual property of the material which enabled it to be modified to individual requirements after it had been softened by boiling.

INTERNATIONAL ABSTRACT OF SURGERY

A wide-bore endotracheal connection which connected the tubes to the anesthesia apparatus was described. The author preferred packing off the pharynx under direct vision with a 3 inch open woven bandage soaked in liquid paraffin rather than the inflatable cuff.

The technique of anesthesia used for several types of injuries was described. Care was taken to treat hemorrhage and shock and to stabilize the patient's blood pressure at 70 mm of mercury or above before the operation was started. Great stress was laid on the need for providing an unobstructed airway in all cases. Sometimes intubation and tracheobronchial suction without anesthesia was necessary to take care of the anoxic emergency.

Pentothal was employed before bromethyline came into use. The technique of its use was described. The tendency to laryngeal spasm was the main drawback to this agent. Although preliminary tracheotomy under local anesthesia was the main procedure in cases of injury to the larynx, edema of the glottis, and heavy edema of the tongue prior to the induction of general anesthesia was an open question among anesthetists. Deliberate tracheotomy was performed as an emergency.

The anesthetic was kept as light as possible throughout the procedure so that the return of the reflexes was as rapid as possible. The maintenance of the anesthesia once induction was completed was usually carried out by a closed technique of carbon dioxide absorption with nitrous oxide-oxygen ether cyclopropane or ether with the Oxford vaporizer. When the anesthesia was terminated every effort was made to provide and maintain a free airway. Often tracheotomy was performed after the operation was completed. The nasal, pharyngeal or oral airway was always left in place in those patients who did not have tracheotomy. The postoperative care of the patient was of utmost importance and revolved around the maintenance of a free airway. In some instances it was necessary to retain the endotracheal tube for periods of time before it was removed. The patient was placed on his side with the head slightly extended, until fully conscious. Suction was always available and care was taken not to depress the respiratory center with too much sedation.

A short recovery period was considered essential, as was individual skilled supervision until the patient was conscious.

LIVINGSTON H. M.: The Present Status of Ethylene Oxygen Anesthesia. *Ann Surg* 945 1:4 1971

The data presented concerns a general evaluation of 18,150 operations done under ethylene anesthesia in which 11,560 cases had ethylene-oxygen alone. A detailed study was made of the last 3,310 consecutive operations done under ethylene-oxygen. The history of the drug was described extensively and the present physical, physiological, and pharmacological results of its use were reviewed.

As to the fire and explosion hazard of the agent it was concluded that the drug showed the same inherent explosive quality that is present in all inhalation agents except chloroform or nitrous oxide. The author emphasized the quiet smooth induction of the anesthetic, the lack of effect on the red cells, hemoglobin, and the coagulation time or character of the blood clot, and the carbon dioxide combining power of the blood. Blood urea, and icteric index. The reaction to ethylene-oxygen was found to be only moderate without asphyxia, and was limited to the second plane of surgical anesthesia.

The amplitude of the contractions of the stomach, small intestine, and colon were increased without change in tone, and there was depressed gastric secretion with delay in the emptying time of the stomach. Death was due to asphyxia with respiratory failure before cardiac failure.

Ethylene produced no spasm due to direct irritation. Electrocardiograph studies showed no evidence of disturbances in cardiac automaticity or conduction. There was no marked stimulation or depression of the vagus center. Ethylene and procaine gave the lowest incidence of arrhythmias in human beings.

There were no anesthetic deaths reported in the series.

Premedication included morphine sulfate (gm 0.010 to 0.015) given hypodermically and calcium nembutal (gm 0.18 to 0.27) per rectum given 1½ hours before anesthesia.

A detailed tabulation was made of the 50 deaths which occurred following the 3,310 operations. The author believed that an excellent test of the drug was made in the series reported because of the major character of the surgical operations performed. There was a notably low incidence of circulatory and respiratory complications. Vomiting was minimal in comparison with ether.

The author concluded that ethylene-oxygen seemed to be definitely a preferable inhalation agent for the poor risk patients including those with cardiopulmonary mechanisms. The reported death rate of ethylene was lower apparently than that of any other inhalation agent. The main drawback of this anesthetic was its deficient muscular relaxation for the average patient.

FLIEB, G.: Percutaneous Spinal Anesthesia Combined with Evipal Narcosis. *Acta chir scand* 1945, 9: 537

The author reports 500 spinal anesthetics with pericaine (nupercaine) in 1 to 1500 dilution combined with evipal narcosis. The method affords ideal working conditions in abdominal surgery, without extension of the spinal anesthesia to dangerous heights. It reduces the risk of both individual patient. It is humane especially for the anxious should a critical condition arise because the needle is in place in the vein. It presents no complicated apparatus, and it secures a more placid awakening.

46	14-15	12-13
44	13-14	11-12
42	13	11
40	12	10

The technique is described in detail. One and one half cubic centimeters of tetracaine (2% solution) (similar to pantopon) and 10 cgm. of ephedrine were given subcutaneously before operation. The patient was placed in a lateral decubitus position and spinal tap effected. The volume of percaine given was determined by means of the above table.

The solution was injected at the rate of 4 c.c. per minute. The needle was left in place in the subarachnoid space and after from 5 to 10 minutes the height of analgesia was tested. If the analgesia was too low a supplemental dose of from 2 to 6 c.c. of percaine solution was administered the needle removed, and the patient turned on his back in a horizontal position or in a few degrees of the Trendelenburg position. Infusion was then initiated and epinal sodium in a 10 per cent solution was injected at approximately 1 c.c. per minute. The aim as a rule was to keep the patient dozing. Saline solution was administered to maintain patency of the needle.

In 91.2 per cent of the cases the effect of the combination of drugs was considered ideal. 8.2 per cent were considered to have a moderate effect and 0.6 per cent had a poor effect. The effect was poorest in men in the age group between 30 and 40 years and in operations above the umbilicus. In 4 cases the epival produced a mild excitation.

The dose of percaine averaged 19.4 c.c. in men and 17 c.c. in women in operations above the umbilicus and 16 c.c. and 15 c.c., respectively in operations below the umbilicus. The largest dose was 32 c.c. administered to a man of 37 years for gastrectomy. The average dose of epival was 8.6 c.c. Twenty-three patients slept satisfactorily on 3 c.c. 15 on 2 c.c. and 1 patient even on 1 c.c.

Complications arising from the combination were few. The blood pressure in most cases remained constant in spite of limited usage of the Trendelenburg position. Eighty-seven per cent of the cases showed a partial fall which did not exceed 30 per cent. 10.8 per cent exhibited a fall between 31 and 50 per cent and 2.3 per cent exhibited hypotension of over 50 per cent. In most cases no changes were demonstrable in the respiration and the pulse also remained unchanged. Vomiting occurred more rarely than in spinal anesthesia alone. Headache was present infrequently.

In 15.6 per cent of the cases the postoperative retention of urine exceeded 24 hours. This high percentage was considered possibly due to the wide use of morphine medication. There were 4 deaths during

the first 24 hours but in no case was anesthesia considered a factor. One death which is perhaps ascribable to the combination anesthesia occurred before the operation was completed.

Parathesia occurred in 1 patient on the seventh day after operation. It was localized to the radial side of the right thumb. Pneumonia was a postoperative complication in 4 cases, 3 of which had a fatal outcome on the seventh, ninth and eleventh days respectively.

The drawbacks to the method include the somewhat long preparation, the need for an experienced anesthetist besides a nurse at the head of the patient and the possibility of unilateral anesthesia.

The method was contraindicated in liver damage, shock conditions and severe morbus cordis, sepsis, tuberculosis and syphilis. MARY KARP, M.D.

Fairclough, W. A. Sixth Nerve Paralysis after Spinal Analgesia. *Brit. M. J.* 1945, 3: 801.

The author briefly reviews the literature concerning the occurrence of sixth nerve paralysis following spinal analgesia, and reports that in a series of 2031 spinal anesthetics 10 instances of partial paralysis were noted. Of all cranial nerve palsies following spinal analgesia, abducens paralysis constitutes well over 90 per cent of those reported. The various theories which have been advanced to account for the vulnerability of the abducens nerve are listed and all of them attribute it to the purely anatomical disadvantages of this nerve.

A new theory is then suggested as to the possible cause for the frequent paralysis seen in this nerve. The factors necessary in binocular stereoscopic single vision are listed and the frequency of some disturbing factor in this complex mechanism is mentioned. Phylogenetically binocular vision is a recently acquired sense and presumably the first lost. The early occurrence of diplopia in unpremeditated inhalation anesthesia and in inebriation is mentioned as an example of the upsetting by a toxic substance of the normal physiological balance necessary for binocular single vision. It is pointed out that the normal power of adduction of the two eyes is three times as strong as the power of abduction. Esophoria is a common form of muscle imbalance. The loss of a part of the tonic impulses conveyed by the abducens nerve could then easily upset the balance and make manifest a squint that had been latent until the introduction of the spinal anesthetic. To explain why most such pareses are unilateral the author states that when the effort to maintain binocular vision is abandoned the second eye is often able to carry on monocular movements normally with the less powerful stimulus being transmitted over the abducens nerve.

Ten cases of partial transient unilateral paralysis of the abducens nerve following spinal analgesia (spinal percaine 1/200—from 1.5 to 3 c.c.) are reported with brief abstracts. Nine of the patients examined after their vision was subjectively normal had an esophoria varying from 1 to 5 I.D. at 6

meters and none had exophoria. The diplopia appeared in from 5 to 21 days after anesthesia and persisted from 2 weeks to 14 months. Covering the affected eye gives relief but is not advised as the removal of the stimulus toward fusion and the re-development of binocular vision is thought to retard recovery. Dark glasses with a covering over the outer third of the glass covering the affected eye are recommended. Muscle exercises and fusion training may be found necessary in those cases in which a natural recovery is delayed.

THOMAS DOUGLASS, M.D.

Engstrand, L. and Friberg, O : On the Function of the Liver as Affected by Various Operations and Anesthetics. *Acta. chir. scand.* 1945 91 3

The liver function was studied postoperatively by means of a series of tests of hippuric acid synthesis (intravenous test) in association with a number of different operations and forms of anesthesia. There was a considerable dissertation on the physiology of the liver and the methods available for the study of its function.

The first group of experiments was made on cases subjected to high spinal anesthesia. It was shown that there was a reduction in the liver function in those cases of high spinal anesthesia (with perclaine) in which a fall in the blood pressure occurred. The cause was considered to be an anoxic injury to the liver.

No reduction of liver function was found with inhalation narcosis with ether a fairly great reduction was observed persisting in most cases for more than a week after the operation. In abdominal operations ether narcosis always appeared to reduce

the liver function even when there was a high glycogen content in the liver during the narcosis and when an adequate supply of oxygen was given during the anesthetic.

The reduction of the hippuric acid synthesis varied according to the magnitude of the operation. Cyclopropane was the anesthetic which was least harmful to the liver even in cases showing a strong reduced liver function preoperatively.

When narcotol nitrogen-monoxide (nitrous oxide) was used with from 15 to 20 per cent oxygen or less, a decrease in the liver function test was manifested, but none appeared when the oxygen administration was 20 per cent or over.

Preoperative and postoperative management with respect to the liver was discussed and the hippuric acid test evaluated. In the cases with strongly reduced liver function it was found important to treat the liver preoperatively for from five to seven days with carbohydrates and proteins, fats being excluded from the food. Glucose was then given subcutaneously on the morning of the operating day. Cyclopropane was considered the anesthetic of choice and an abundant supply of oxygen was continued throughout the operation. Postoperatively a glucose drip was retained for from 4 to 6 days and plasma transfusion was administered in the cases with disturbances of the serum protein content. From the third postoperative day on, fat was included in the food along with a high carbohydrate diet. Although cyclopropane was the agent of choice in these cases, local anesthesia plus narcotol nitrogen monoxide oxygen could be employed if adequate oxygen was administered throughout, but ether was definitely contraindicated.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Curtis, G. M., and Fertman, M. B.: Blood Iodine Studies. *Ann. Surg.* 1945, 130: 963

This paper is one of a series of reports on fundamental metabolic studies. The relation of the basal metabolic rate to the blood iodine in a large variety of thyroid diseases was investigated.

The authors conclude that the basal metabolic rate is a more reliable test of thyroid activity than is the estimation of the level of the unfractionated whole blood iodine. However they state that both determinations, considered together are superior to either one alone.

Although the basal metabolic rate is elevated in all forms of toxic goiter, it is increased more in exophthalmic goiter than in any other form of goiter with hyperthyroidism despite a similarity in the extent of increase of the average unfractionated whole blood iodine in all forms of toxic goiter.

VanOrdstrand, H. S., Hughes, R., DeNardi, J. M., and Carmody, M. G.: Beryllium Poisoning. *J. Am. Med. Ass.* 1945, 139: 1084.

A disease entity beryllium poisoning has been encountered in workers in the beryllium industry. In three plants in the Cleveland area 170 workers have been affected by dermatological and/or respiratory tract manifestations of this disease. When the respiratory tract is involved the disease may progress to a syndrome resembling chemical pneumonitis. This development caused the death of 5 workers.

JOHN J. MALONEY, M.D.

Schafer, P. W.: The Etiology and Treatment of Polycythemia Rubra Vera. *Ann. Surg.* 1945, 122: 998.

By means of protriocceptor depressor neurotomy, a form of absolute polycythemia has been produced experimentally in dogs. This form of experimental polycythemia disappeared following extensive paravertebral sympathectomy. Support is thus given to the theory that the normal, and some abnormal formation of red blood cells by the bone marrow is under the control of the sympathetic nervous system through its regulation of the caliber of the pre-sinusoidal vessels of the marrow.

The theory is advanced that some cases of polycythemia rubra vera in man are due to constriction of the pre-sinusoidal blood vessels of the bone marrow and extensive paravertebral sympathectomy is proposed as treatment for this disease. The successful result of treatment of 1 man with polycythemia rubra vera by extensive paravertebral sympathectomy is then reported.

SAMUEL KATZ, M.D.

Tyson, M. C., Vogel, P. and Rosenthal, N.: The Value of Penicillin in the Treatment of Aggranulocytosis Caused by Thioracil. *Blood, J. Hemat.*, 1946, 1: 53.

Since 1943 when Atwood found that thioracil effectively inhibited the function of the thyroid gland, this drug has come into increasing favor in the clinical treatment of hyperthyroidism. In severe hyperthyroidism this agent reduces the basal metabolic rate and brings about clinical improvement. Of all the thyroid depressing drugs thus far tested, thioracil seems to be the least toxic. However, sufficient cases have been reported to demonstrate convincingly that thioracil may affect the bone marrow in such a manner as to induce a severe or even fatal aggranulocytosis. During his preliminary experiments, Atwood noted 1 patient who had been given a relatively large dose of thioracil and developed aggranulocytosis. This complication has been observed with varying frequency in later series of cases.

The present authors believe that the use of thioracil is more dangerous than a survey of the literature would indicate. Of 54 cases treated with the drug at Mount Sinai Hospital, New York, 6 (approximately 11 per cent) developed aggranulocytosis. Three additional cases of postthioracil aggranulocytosis came under the care of the authors. In spite of treatment, 4 of the 9 cases studied were fatal. 5 patients recovered after penicillin therapy. Since penicillin has no deleterious effect on the bone marrow, the authors believe that it is ideal for all cases of aggranulocytosis and especially for those that may have resulted from chemotherapy with thioracil, sulfonamide, aminopyrine, or other drugs.

This article calls attention to a number of important concepts that may be summarized as follows:

1 The cases that developed aggranulocytosis had received thioracil for at least 5 to 6 weeks before symptoms of the complication appeared.

2 In the treatment of aggranulocytosis, penicillin is apparently effective in so far as it combats the bacterial invasion and toxemia, and enables the patient to survive until the bone marrow has regenerated.

3 In attempting to explain why some patients develop sensitivity to the drug and others do not, it is suggested that the cumulative effect of the drug may cause sensitivity and subsequent toxic action on the myeloid elements of the bone marrow.

4. While there is no question that under certain conditions thioracil is an excellent drug to tide a patient over an acute episode of thyrotoxicosis, and especially in preparation for thyroidectomy its effectiveness is present only during its administration. It cannot be considered as a medical cure, since it does not affect the basic difficulty of thyrotoxicosis."

MISCELLANEOUS

5. One can predict that in the future there will be an increasing number of cases of agranulocytosis since additional courses of the drug will be an opportunity for more patients to be sensitized to the recurrence takes place and there will thus be an opportunity for more patients to be sensitized to the drug. For this reason it would seem advisable at present to limit the use of the drug only to selected preoperative cases and those in which operation is contraindicated.

Kilne, B. E. Miller J. A., Rusch H. P. and Baumann C. A.: The Carcinogenicity of p-Dimethylaminobenzene in Diets Containing the Fatty Acids of Hydrogenated Coconut Oil or of Corn Oil. *Cancer Res.* 1946 6:1

Ten groups of rats each were fed various lipids in synthetic diets containing 0.06 per cent of p-dimethylaminobenzene for 4 months and these diets were then followed by a dye-free diet for 2 more months.

When 2.4 per cent of lauric acid or 4.7 per cent of the fatty acids of hydrogenated coconut oil were fed, no liver tumors developed within 6 months. If, however, these lipids were replaced by 5 per cent of corn oil, or by 4.8 per cent of the fatty acids of corn oil, the tumor incidence at 6 months was 80 and 53 per cent respectively.

The presence of 5 per cent of olive oil or 4.5 per cent of oleic acid in the diet resulted in a tumor incidence of from 33 to 53 per cent, and 87 per cent, respectively at 6 months. Twenty per cent of the rats fed on a diet free of added fats developed hepaticomas within this time.

SAWART KATZ M.D.

Sugarbaker E. D. The Surgical Problem of Cancer in the Lymph Nodes. *Surgery* 1945 18:668.

This article deals with the problem of the treatment of cancer in the lymph nodes in an attempt to determine how such treatment may be developed to maximum advantage. Considerable divergence of opinion prevails concerning the ideal plan of treatment of occult cancer in the lymph nodes. There is no doubt that the lymph node is an important character of the nodes indicates lymph node involvement. Prophylactic dissection implies that the nodes are suspected of containing carcinoma cells despite the absence of physical signs of node involvement. It is apparent that in both instances errors in diagnosis will occur. There is a wide variation in the frequency with which different sites of primary tumor involve the lymph nodes. Different sites of primary tumor involve the lymph nodes differently, the lymphatic systems of the parts, the size of the lesion, whether the tumor is primary or recurrent, the nature of previous treatment, and the duration of symptoms must all be taken into consideration. The node incidence in some of the commoner tumors is given in Table I.

Another consideration not discussed in the literature but which seems to be pertinent to the problem relates to quantitative node involvement in dissection specimens from the various tumors and the

TABLE I THE NODE INCIDENCE OF CANCER

Tumor	Per Cent
Cardioma, intrinsic larynx	10
Carcinoma, skin	15 to 15
Carcinoma, penis	25
Carcinoma, lip	31
Carcinoma, lower gingiva	35
Carcinoma, buccal mucosa	40
Carcinoma, vulva	46
Carcinoma, tongue and floor of mouth	63
Melanoma, skin	64
Carcinoma, rectum	68
Carcinoma, colon	70
Carcinoma, extrinsic larynx	70
Carcinoma, stomach	75
Carcinoma, breast	75
Carcinoma, tonsil	77
Carcinoma, nasopharynx	80

relative frequency with which widespread metastases occur. A table showing the average number of nodes involved for different types of cases and the per cent of cases with more than one node involved is presented in the original article. It seems reasonable that if a given tumor metastasizes with regularity to only one or two nodes, remains confined there after all clinical doubt as to its presence has been dispelled and very rarely kills by reason of more widespread dissemination, then such a tumor might as well be treated by a dissection done there peccatically instead of prophylactically. Conversely, when a tumor metastasizes regularly to the local nodes before its presence becomes clinically apparent, it is found to involve numerous nodes of the specimens examined and not infrequently brings about death by distant spread, dissection must be carried out prophylactically if it is to be of any use at all. Therefore it is apparent that the problem is concerned not only with how frequently regional nodes are involved but also with how rapidly the disease is apt to spread beyond the limits of the removable chain.

In many instances the anatomy is so adaptable that removal of the primary tumor with the regional nodes becomes little more of a task than removal of the primary tumor alone. This is true of the stomach, bowel, and lungs. The question of node dissection therefore pertains mainly to those tumors in which the primary and node area are best treated separately either at one sitting or in stages. Consideration must be given to the relative value of the several major dissections—cervical, axillary and inguinal—based on the anatomy peculiar to each and the way they tend themselves to node dissection. One must also consider the added risk of prophylactic node dissection in poor risk patients in the cancer age group.

In the surgery of cancer there are in general, two major problems (1) the degree of radicality required by the tumor and (2) the degree of radicality which the patient will withstand. Overestimation of the first and underestimation of the second will result in too high a percentage of postoperative fatalities.

The converse will result in too low a percentage of cured cases. Contraindications to therapeutic and prophylactic needle section are presented as well as the arguments for and against prophylactic dissection in cancer of the lip.

JOHN L. LINDGREN, M.D.

GENERAL BACTERIAL, PROTOZOAN AND PARASITIC INFECTIONS

Epidemiology Unit Number 22 Sulfadiazine Prophylaxis and Resistant Streptococci *J Am Med Ass* 1945 129 921

A previous article has described the pronounced reduction of streptococcal disease which occurred at a large naval training center in the Northwest as the result of sulfadiazine prophylaxis. The present report deals with the loss of effectiveness of this prophylaxis due to the appearance of sulfadiazine resistant strains.

After approximately 3 months of successful sulfadiazine prophylaxis the effectiveness of this large naval training center the effectiveness of this prophylaxis became progressively less and eventually a major epidemic of streptococcal disease occurred. An increase in dosage to as high as 3 gm. daily did not prevent streptococcal diseases and it was the impression of medical officers at the center that the drug had lost its value therapeutically in these infections.

The loss of prophylactic value of sulfadiazine was originally associated with an absolute and relative increase in the frequency of group A type 10 infections to the practical exclusion of all other types. Later group A type 17 became relatively frequent. These two types were shown by laboratory methods to be sulfonamide resistant *in vitro*.

Other types of streptococci with a few exceptions of type 3 were not sulfonamide resistant.

The proportion of sulfadiazine resistant strains was greater in those recruit camps getting sulfadiazine prophylaxis than in those not getting sulfadiazine.

There was some suggestive evidence but no definite proof that in the presence of sulfadiazine resistant strains sulfadiazine prophylaxis tended to increase the streptococcal infections, particularly scarlet fever.

DUCTLESS GLANDS

Shibley, E. G. and Ransfield, A. N.: Glucose Tolerance in Rats following Repeated Small Doses of Alloxan. *Endocrinology* 1945 37 373

This article deals with purely laboratory research of glucose tolerance in rats with repeated small doses of alloxan. It has been shown conclusively that a single injection of a large dose of alloxan (from 200 to 400 mgm/kgm) administered subcutaneously produced severe and permanent diabetes in rats with necrosis of the beta cells in the pancreatic islet (Dunn, Sheehan and McLetchie 1933; Golner and

Gomori 1935). Single intravenous injections of from 60 to 75 mgm/kgm produced equally severe diabetes in rats (Shibley and Meyer unpublished data).

The effect of small repeated doses of alloxan on the functional capacity of the islet is not yet certain. The authors quote the literature on this particular phase of this research and claim that give their procedure of injecting small doses of alloxan in definite control groups of rats. They then discuss their results and give tables showing the results. They have reached the following conclusions:

Rats given 15 subdiabetogenic doses of alloxan over a period of 4 weeks did not become hyperglycemic on a normal diet but showed impaired tolerance to administered glucose.

The decrease in tolerance to glucose appeared to be permanent since it remained 1 to 2 1/2 weeks after cessation of the alloxan treatment.

In a second group of rats there was a marked progressive decrease in glucose tolerance after each injection of a 25 mgm/kgm dose of alloxan. The decrease in glucose tolerance was shown by the higher blood glucose levels reached early in the test and in the slower return of the glucose level to normal.

It was concluded that 25 mgm/kgm doses of alloxan given intravenously produced a progressive damage to the pancreatic islets in rat and that even a small amount of damage was not followed by compensatory reaction.

Extract from the anterior pituitary tube administered to 4 rats with impaired glucose tolerance produced hyperglycemia after 11 days in 3 of the animals.

PETER MARRAS, M.D.

Ungar, G.: Endocrine Function of the Spleen and Its Participation in the Pituitary-Adrenal Response to Stress. *Endocrinology* 1945 37 3

As a part of the problem of the spleen as an endocrine organ has been suspected for a long time. Extensive reviews of the problem by Landis (1931) and by Perla and Marmorstein in 1935 showed, however, that in spite of a great deal of circumstantial evidence there was no solid proof of an internal secretion of the spleen. The last 10 years or so seem to have brought forward any solid evidence it may be a matter that the first experimental evidence article can attribute the first experimental evidence that the spleen produces and can release into the circulation a substance acting like a hormone. It also shown that this function of the spleen is under the control of the pituitary gland and that the adrenal cortex. The significance of the internal secretion of the spleen is not yet quite clear but all the data tend to the conclusion that it is produced in case of emergency and its main action is on the protein metabolism.

The author describes his method of attacking this research problem and gives the results of his response to tissue injury hemorrhage, starvation

MISCELLANEOUS

and drug actions. The results of these suggested that under the influence of certain stimuli a reaction took place involving the pituitary, the adrenal cortex and the spleen. The question then was whether the spleen played its part by releasing the active substance or by causing some other reaction. A crude extract of guinea pig spleen in saline solution was prepared and injected subcutaneously in order to study its effect on the bleeding time of guinea pigs. The mode of action of the spleen was studied and found to have the following effects: (1) it reduced the bleeding time (2) it increased the capillary resistance and (3) it inhibited the histamine release from the blood cells. The author summarizes his observations and concludes as follows:

In the course of a study of the pituitary-adrenal reaction to stress this response was found to be inhibited by splenectomy. It was also observed that spleen extracts contain an active substance which can reproduce the reaction to the original stimulus. This active substance was isolated and obtained in pure crystalline form. It is probably part of the antihemolytic system which protects proteins against trypsin. The spleen as an endocrine organ may therefore play a part in the control of protein metabolism and its adjustment to conditions of stress.

PATL MERRILL M.D.

SURGICAL PATHOLOGY AND DIAGNOSIS

Bowden R. E. M. and Gutmann E. The Clinical Value of Muscle Biopsies. *Lancet* Lond 1945 349 768

The authors note that there are several medical and surgical conditions in which examination of biopsy specimens of muscle is helpful or even essential in the establishment of a diagnosis but until recently this method has been largely neglected in the investigation of neuromuscular disorders. In certain cases of paralysis associated with vascular lesions, the value of muscle biopsies has been demonstrated. In peripheral nerve injuries they have yielded information which has been of great assistance in diagnosis, prognosis, and treatment. In paralysis of gradual onset it may sometimes be difficult to determine whether the lesion is primarily neurogenic or myogenic and in such cases even electrical reactions and electromyography sometimes do not give decisive information. Besides giving information about the state of the muscle fibers a muscle biopsy is a form of nerve biopsy in that nerve fibers, empty Schwann tubes or motor end plates are almost always found among the muscle fibers.

The authors state that the purpose of this article is to indicate the value of muscle biopsies in the diagnosis, prognosis, and treatment of neuromuscular disorders. Four types of cases have been investigated: (1) lower motor neurone lesions due to peripheral nerve injuries, (2) lower motor neurone lesions other than peripheral nerve injuries, (3) primary muscular disorders and (4) vascular lesions.

Some illustrative cases are described and summaries given of the indications for performing biopsies, the methods of treating specimens and the findings.

The indications for performing a muscle biopsy may be summarized as follows:

1 To determine the state of muscles in which atrophy is advanced or in which a vascular lesion is suspected and if the latter is found to assess the type and severity of the lesion. Surgical repair of nerves or long continued physical treatment is valuable if the muscles have been irreparably damaged.

2 To aid in the diagnosis of the type of lesion in the nerve and to determine whether satisfactory regeneration is taking place in partial or recovering lesions.

3 To differentiate between paralysis of myogenic origin and disease of the lower motor neurone.

4 There are special indications for the use of biopsies in certain cases of poliomyelitis as detailed by the authors.

A method of muscle biopsy is presented. The histological findings that are found typical of the types of cases that have been investigated and have been reported herewith are described. In their discussions of the effect of vascular lesions of muscle, the authors state that there is still a difference of opinion about the mechanism underlying vascular lesions of muscle, but from experimental and clinical observations it is evident that two main types of lesions must be recognized: (1) those due to interruption of the arterial supply and (2) those following venous obstruction. A sudden complete obstruction of the artery will cause necrosis of the muscle fibers. If the lesion is the result of venous obstruction, the picture is one of dense fibrous tissue proliferation but there is no clear cut boundary of the affected area. Clearly, in either type of lesion there is a poor prospect of recovery if the changes are widespread. Many vascular lesions are complicated by degenerative lesions of the nerve trunks. In such cases the prognosis is much less favorable.

Finally the limitations of muscle biopsy are presented. It is noted that a biopsy specimen is a small sample. Furthermore, a biopsy specimen may contain no nerve elements. Sufficient time must elapse for regeneration of nerve fibers if biopsy is to be used to determine whether this process is progressing satisfactorily. When a nerve lesion is at a high level it may not be justifiable to wait for biopsy before proceeding to direct exploration of the nerve.

EXPERIMENTAL SURGERY

Duguid J. P.: The Numbers and Sites of Origin of the Droplets Expelled during Expiratory Activities. *Edinburgh M. J.* 1945 53 385

The number of droplets expelled during normal breathing, strong nasal expiration, laughing, speaking, coughing and sneezing has been estimated by four different methods.

- 1 Counting the colonies on culture plates exposed directly to the droplet spray
- 2 Counting the droplet stain marks on slides exposed directly to the droplet spray. This gives the number of all droplets larger than about 20 microns in diameter
- 3 Counting the colonies on culture plates exposed in the Bourdillon slit sampler. This gives the number of bacteria carrying droplets small enough (with initial diameters under about 100 microns) to remain air borne as droplet nuclei.

4 Counting all microscopically visible droplet nuclei found on oiled slides exposed in the slit sampler the nuclei being colored by dye previously taken into the mouth. This new method gives the numbers of droplets with initial diameters between about 1 and 100 microns and these counts are considerably greater than the counts obtained by any other method. The numbers of droplets originating from the nose and throat were estimated in tests with bacillus prodigiosus inoculated as an indicator on to one of the sites.

No droplets were found to be expelled by normal mouth breathing for a 1 minute period. Normal nose breathing for a 5 minute period sometimes did not produce any droplets, and sometimes produced a few these droplets were found to originate in the nose. A single strong nasal expiration produced from a few to a few hundred droplets some of these were small enough to form droplet nuclei.

Laughing for a one minute period sometimes did not produce any droplets and sometimes produced a few these originated in the faucial region. A few these were produced from a few to a few dozen droplets counting loudly produced from a few dozen to a few hundred these apparently originated in the front of the mouth and were small

enough to form droplet nuclei. Saying 100 K. loudly sometimes produced a few dozen or a few hundred droplets many of these originated in the faucial region, and a few of the faucial droplets were small enough to form droplet nuclei.

A single cough with the mouth kept well open, sometimes did not produce any droplets, but sometimes produced a few dozen or a few hundred. Many of these originated in the faucial region, and a few were small enough to form droplet nuclei. A single cough with the mouth initially closed produced from a few hundred to many thousand droplets these originated in the front of the mouth and were small enough to form droplet nuclei.

A single natural sneeze produced from a few hundred thousand to a few million droplets these apparently originated in the front of the mouth, and were small enough to form droplet nuclei. In most sneezes, between a few and a few thousand droplets were found to originate both from the nose and from the faucial region some of these also were small enough to form droplet nuclei.

Thus, speaking, coughing, and sneezing produce many droplets small enough to remain air borne as droplet nuclei. Nearly all of these small droplets originate in the front of the mouth. The extent of air borne infection which may be produced by the droplet spray of infected persons, therefore, must depend largely upon the frequency with which pathogenic organisms are present in the secretions of the anterior mouth. This frequency does not appear to be great. The hazard of air infection with droplets originating in the nose or throat, where pathogenic organisms are often present in great numbers is limited by the small amount of atomization which is found to take place at these sites.

A DISCUSSION OF CONTROVERSIAL POINTS IN AMPUTATION SURGERY

FRANCIS M. MCKEEVER, M.D., Battle Creek, Michigan

THERE is great difference of opinion between surgeons concerning the various procedures of amputation surgery. Some disagree concerning only minor variations in technique or unimportant matters of personal preference. Others differ in matters of basic importance. In time of war because amputation is frequently necessary after severe injuries from high velocity missiles great experience is gained in this field of surgery.

At Percy Jones General Hospital in the 33 month period from January 1943 to October 1945 the amputation service has cared for 2,783 patients with major amputations. This is a greater number of amputees than was cared for by the entire Medical Department of the United States Army during World War I which produced only 2,635 amputees. These 2,783 patients had a total of 2,988 amputated extremities. The incidence of amputation per patient and the location of the extremities which were lost are presented in Table I.

As a result of this experience many procedures and techniques of amputation surgery which are controversial have been observed. Observation of this group of patients has established that certain methods have a definite value while others give less favorable results.

OPEN CIRCULAR AMPUTATION

In the United States Army Medical Corps the open circular amputation or as it is more commonly and less accurately termed guillotine amputation was mandatory in all instances of amputation for trauma in forward installations. In this type open operation the skin is cut circularly at the lowest level of good tissue and allowed to retract. The fascia is then incised at the line of skin retraction and the superficial muscles are sectioned and allowed to retract. The deeper muscles are then sectioned at the line of retraction of the superficial muscles and allowed to retract. The bone is then cut through at the line of muscle retraction. *The leg is not chopped off as if by a cleaver.* This procedure carried out

correctly produces a potentially inverted cone when traction is applied to the skin but leaves no flaps to trap infection. If the patient is given proper postoperative care the essential of which is traction the stump is usually ready for definitive surgery in 8 weeks. If constant traction is not applied muscles retract and a large section of bone protrudes from the end of the stump (Figs. 1 to 4).

The flap type of open operation in which overhanging duck bill flaps are produced was forbidden in the American Army forward hospitals. The British Army permitted its surgeons to do the so called flap guillotine operation as they deemed it advisable. Many American surgeons both in military and civilian practice have taken exception to the absolute deletion of the flap type operation in forward hospitals and there has been considerable heated debate around this point. It was claimed that it was out of the question to keep traction on the open circular amputation, and that stumps resulting from this type of open operation would arrive in poor condition in the Zone of the Interior. This objection was not valid. In 3 years and in 2 783 patients with 2 988 stumps there were 30 stumps, or 1 per cent, which had not had the proper postoperative care by the time they arrived at this Midwestern hospital. Many of these patients arrived at the Zone of Interior hospital with effective traction still on the stump having crossed half of Europe the Atlantic or Pacific Ocean and half of this country with very ingenious combinations of adhesive tape plaster and elastic bands to keep the skin from retracting.

The only valid arguments for the flap type of open operation are (1) time, (2) the avoidance of a second operation. The argument of time is valid in that if the immediate convalescence is not complicated by severe sepsis, early secondary closure is possible. In some instances after the first 10 days to 2 weeks the flaps can be permitted to fall together and be loosely sutured thus obtaining a closed stump soon after the injury. The second point is not a valid argument in very many instances. A high percentage of amputation stumps resulting from the secondary closure of inaccurately cut flaps will be poor stumps, with

too much redundant skin and muscle at their ends. This condition will require a late secondary operative procedure to produce the ideal stump. A young vigorous man is going to and must, use his prosthesis hard. He cannot get by with a poorly tailored stump. For the aged individual who will probably use a prosthesis very occasionally and in whom the avoidance of surgical incidents is desirable, the flap type open operation may have added merit. For the young in whom perfection of stump is desired the open circular amputation is believed superior as in this method a late definitive operation is an accepted fact.

In amputations done for trauma, the danger of ever present infection becoming invasive and virulent is reduced to an absolute minimum by the perfect drainage afforded by the open circular operation. The definitive surgery to complete the closure of an open circular amputation is in effect a late secondary wound closure. Whether it be accomplished by plastic closure or by reamputation at site of election it is associated with very little danger. In carrying out the definitive or final operation in 2 988 stumps in 2 783 patients who had had an open circular amputation a severe recrudescence of infection in the amputated extremity as manifested by cellulitis, abscess, high febrile reaction and general sepsis, occurred in only 20 instances, or 0.66 per cent. No patient died as a result of the definitive surgery on the guillotine stump.

Five per cent of patients had some complication of their final surgery. The common complications were a mildly infected hematoma in the stump without systemic reaction or a marginal skin necrosis which required a minor skin plastic later. Most of the patients with the complication of hematoma on its evacuation after the removal of a few stitches recovered with a satisfactory stump and without further surgery.

The severe infections resulting from secondary closure or reamputation occurred many times where they were least anticipated. Some were in a stump which had been completely healed for many months or had been covered by a skin graft for many months. Other stumps which had more than a reasonable amount of granulation tissue at their

end at the time of surgical revision convalesced with no reaction. The only inference to draw from this is that regardless of how nearly normal the condition of previously infected tissues may appear it is never free of bacteria and those bacteria may become rampant at any time.

All patients received for 48 hours prior to surgery either sulfonamides or penicillin systemically. They also received one or the other of these antibiotics for as long postoperatively as was indicated by their general condition or the local condition of the operative site. Sulfadiazine was the sulfonamide used. About 1,800 patients received sulfadiazine and 1,000 penicillin. The patients preferred sulfadiazine to escape being punctured with a needle. One seemed about as effective as the other in this type of surgery and a positive stand for either to the exclusion of the other was impossible. One or the other however should be used. In 500 operations sulfonamides were used topically in the stump. Late in 1943 the topical use of sulfanilamides was discontinued. Since discontinuing the topical use of sulfonamides, the stumps healed better with less reaction and less hematoma.

TECHNIQUE OF AMPUTATION

Opinion differs greatly regarding the actual technical steps of performing an amputation. As one reads surgical treatises on this subject

Fig. 4. Method of applying skin traction to open circular amputation. The stockinette is glued to the skin before patient leaves the operating table and traction is started immediately.

Fig. 5. a, left, Anteroposterior view. b, Lateral view. Good tapered below knee stump. Skin, nonadherent, no bulbous muscle over end, no bony prominences, no superficial neuromas.

the impression cannot be escaped that much has been carried through the years from book to book which does not hold in the light of present physiological and pathological fact.

The surgical technique of amputation should aim to produce a stump which has soft flexible nonadherent skin and which has no redundant muscle. There should result no projecting bony prominences and the neuromas of all nerves should be well covered and not subject to pressure.

In order to avoid adherent skin dissection of the skin flap in the subcutaneous plane must be avoided as much as possible. A certain amount of freeing of the skin to effect a smooth closure is necessary but this rarely needs to exceed 3 centimeters from the skin flap's distal end. As nearly as possible the skin should be left attached to the fascia.

Wherever possible fascia should be closed over the bone end. In many instances of secondary closure this is impossible. Either fascia and skin or skin alone should be the only covering of the bone end. Muscle should never be used to cover the bone end as it results in a redundant unattached sliding mass at the end of the stump which shrinks very slowly and ultimately turns to scarred avascular tissue. All muscle should be coned out at least perpendicular to the bone end and preferably with its periphery slightly proximal to the bone end. Even in the avascular stump the presence of excess muscle in no way aids the skin circulation, as there are no perforating arteries between muscle and skin.

Some controversy exists relative to the treatment of the bone end. Aperiosteal technique has for years been advocated. By this is meant the removal of a cuff of periosteum about the periphery of the end of the bone. The cuff is variously recommended to be a quarter to one half inch in width. This procedure does not seem a logical one as it deprives the underlying bone of a certain amount of blood supply. In the presence of any sepsis it will in a high percentage of patients, result in a ring sequestrum. The procedure is therefore contraindicated in any secondary closure or secondary reamputation, or in any patient in whom there is any chance of an infected hematoma. Even in the absence of all infection in some instances a ring sequestrum will form because of the avascular necrosis of the bone end, which has been deprived of periosteum.

The periosteum should be incised cleanly at the saw line and at the completion of the bone section the periosteum should be adherent to the end of the bone about its entire circumference. The only reason for the removal of any periosteum from the bone end is that the handling of this membrane has been faulty and rough, thus necessitating the removal of tags stripped loose.

Hemostasis is of utmost importance to the end result of an amputation. Time should be spent tying all small muscle bleeders individually. The development of a moderate hematoma may delay recovery many weeks and even necessitate further surgery. To avoid the collection of blood even after careful hemostasis, it is well to drain the stump with a small rubber drain for 48 hours. Many amputations are done under spinal anesthesia, and a reduced blood pressure may lead the surgeon to a false evaluation of hemostasis. It is well to know the patient's arterial tension before the wound is closed and if it is 20 to 30 millimeters below his preoperative pressure, to have it raised to normal by an injection of ephedrine before the flaps are closed. This will often make what appeared a dry field bleed profusely.

No point in surgical technique has caused as much debate as the method of treatment of the nerve end. This debate has undoubtedly

resulted from the distressing sequela of 'phantom limb. Many chemicals have been advocated for injection into the nerve to prevent neuromas. The true honored method of alcohol injection has had a long period of usage. British authorities have in recent years advocated the use of formalin as a neurotoxic injection. A Russian school has advocated the cauterization of the artery of the nerve proximal to its distal end. Duck bill closures have been described. More recently a method of burying the nerve end in the medullary canal of the bone was described (Figs 6 to 9).

It is well established that there is no chemical which will prevent the end of the cut nerve from healing by neuroma formation. I am unable to comment on the Russian method of depriving the tip end of the nerve of blood supply but believe it only places the neuroma more proximally. The recently advised method of burying the nerve ends in the medullary canal of the bone is open to great objection if the nerve crosses a joint in the stump as it could easily lead to a nerve put under traction in many motions of the extremity.

For the past 3 years in the Amputation Service at Percy Jones Hospital none of these methods has been used. In fact little or nothing has been done to the nerves in an amputation stump except to treat them with

respect and to hide their ends. The nerve should not be forcefully stretched so that it can be cut off high and then allowed to retract so that it will return to its normal length. Rather the nerve trunk should be dissected and cut off high so that the neuroma which will inevitably result in the natural healing of the nerve end is well recessed in muscle. If a large bleeding vessel is present in the nerve this should be ligated.

PHANTOM LIMB SYNDROME

In 2 988 amputations there have occurred 15 neuromas which required surgical removal and these could probably have been avoided had the surgeon been a little more thorough in the original operation. The only indication for the surgical removal of a neuroma is a superficial location which would cause it to be subjected to pressure thus producing pain. This pressure may come either from the prosthesis or as a result of the bare stump resting on or striking a hard surface and can be demonstrated by palpating and tapping the neuroma, which will produce a shock like sensation. The removal of neuromas for the treatment of any phase of the 'painful phantom limb syndrome' will result in failure.

In this group of 2 783 patients 4 instances of painful phantom limb syndrome have

occurred. Undoubtedly more instances of this distressing complication will occur in this group of patients as the years go on. A certain degree of phantom limb sensation seems to be almost physiological and this fact should be appreciated.

Every individual with an amputation has a phantom limb. Rarely does an individual with an amputation have a 'painful phantom limb'. This phantom sensation has a fairly uniform life history. It is present as a complaint in the days immediately following amputation and is usually more severe when the amputation has resulted from crushing trauma or is accompanied by great suppuration.

As healing progresses and inflammation and induration recede the patient complains less of the phantom pain. He will tell you that he has the foot or hand but that it does not bother him. After the phantom has lessened and the patient has learned to live with it, any surgical procedure on the stump will aggravate the phantom phenomenon temporarily. This fact is true even though the surgical procedure in no way involves the nerve end. In many instances a simple excision of a skin scar in this group of patients resulted in an exacerbation of phantom pains. As healing again ensued the disagreeable aspect of the phantom subsided.

When the patient puts on a prosthesis and uses it successfully the phantom phenomenon rapidly assumes a less prominent place in his scheme of life. In fact many patients will proffer the information that the phantom is a help to them. It gives them some inkling of where their foot or hand is and what position it is assuming. This is the ordinary history of the phantom phenomenon.

The rare individual with the abnormal persistent 'painful phantom limb' must be distinguished from the common group who have the normal residual. Although rare this type of patient is not hard to distinguish. Many times the distinction can be made by the patient's scars. Too often such a patient presents scars of removal of neuromas and section of nerve trunks at various levels in the stump. At the base of the extremity the scar of a surgical attack on the sympathetic

nervous system may be present. In addition to these scars he may also present the pigmented marks of the morphine needle. The cure of a truly painful phantom limb by any surgery is extremely dubious. Certainly there is no basis for excision of neuromas or peripheral nerve section in the treatment of this complication of amputation and sympathetic interruption does not have any great number of successes to recommend it. Whether the newly advised operations attacking the cerebral cortex will prove of value is not known.

Probably the only successful treatment of this problem is its prevention. Unfortunately this cannot always be done by the surgeon as it is impossible for him to control the environment of his patients. However in the early management of an amputee he can use narcotics judiciously and take all surgical measures to reduce and shorten extensive suppuration and tissue necrosis. It is almost universal that the picture of painful phantom limb is associated with the use of morphine or alcohol and with the poor adjustment of an individual to his environment. No surgery devised to date offers a cure for these unfortunates.

The following case history is illustrative of the complex nature of these patients.

A paratrooper lost his right arm in combat. He was a very little individual who had a great record for valor. His arm was knocked off by an 88 millimeter shell and a companion applied a tourniquet. Following this he continued in combat for the next few hours until he was wounded in the thigh.

On admission to a hospital in the United States he was cheerful, hard to keep track of and was all over the building. He had no complaints about his arm. He always seemed to enjoy talking about combat and his personal exploits. His amputation stump was revised and he was fitted with an artificial limb, which he used with great dexterity despite a very short stump.

After using his prosthesis for about 6 weeks he announced that he was returning to duty with the paratroops. This was most unusual but it seemed that while on vacation from the hospital he had gone to a paratroop base where he contacted some commanding officer who asked for his return to duty. While on this leave he had also made some jumps.

Two months after leaving the hospital for duty he returned complaining bitterly and constantly that the fingers of his hand were clenched in the palm and that the nails were cutting the flesh and burning like fire. He could not sleep and paced the floor the

typical picture of the painful phantom limb syndrome.

On questioning this patient about the onset of the trouble he related the following story. After going to duty he did well and had no trouble. He had joined a paratroop battalion. After training with them he had finally talked his superior officers into sending him overseas again with the combatants. He arrived at the Port of Embarkation. Here he was given a medical examination. The examining medical officer put his hand on the prosthesis and as he did so said, "You can't go overseas with a wooden arm." The patient amputee said that at that instant he became infuriated that the fingers of his amputated extremity dug into the palm of the absent hand with excruciating pain and that if his arm had been his own he would have slugged the damn doctor. This pain pattern had persisted since this disappointment.

This patient insisted his pains were due to palpable neuromas in the stump. At his insistence and with great skepticism these neuromas were removed. His complaints continued unabated. Then one day about 2 months after the removal of the neuromas out of clear sky he came to the Medical Officer in the ward with a telegram in his hand and announced that he was cured. He stated emphatically that he had no discomfort in his stump and no phantom sensation. To demonstrate his recovery he waved his prosthesis around and lifted a table off the floor with it. It had been impossible prior to this to get the patient to wear the prosthesis. The telegram which he had received was an order from a relief organization for him to go overseas for duty with them in the Zone of Activity.

This case history is well worth remembering. It does not infer that knowledge concerning the painful phantom limb syn-

drome is complete and that there may not come in the future some organic approach to this distressing problem. At present, however, the painful phantom limb syndrome should be listed as a condition not relieved by surgical treatment. A careful analysis of all these patients will reveal one or all of the following factors to play a prominent rôle: viz. drugs, alcohol or severe maladjustment and frustration.

SKIN GRAFTS IN AMPUTATIONS

There has been some advocacy of the use of split skin grafts to hasten healing of open amputations and also of the use of pedicle grafts to conserve length in a short stump. No type of skin graft will stand the wear of a prosthesis and under no circumstances is even a pedicle graft a justifiable final procedure in the lower extremity. There may be rare instances in the upper extremity in which a pedicle graft will preserve valuable length. In the arm the wear and tear from the prosthesis is not so great and the circulation of the stump is usually superior to the lower extremity.

Split grafts have been advocated to produce early healing of open amputations and shorten the time of invalidism. Split grafts can be successfully applied early to open amputation stumps. However, if these stumps are given the proper postoperative attention by keeping

traction applied a split graft is not necessary. The use of split skin grafts to produce early healing does not make the final surgery for an open amputation easier but more difficult. The normal skin rather than coming over the end, as it does with traction, recedes to the margin of the skin graft. Consequently when the final surgery is done there is a paucity of normal skin and the result is that useful bone length must be sacrificed. If a severely traumatized or burned extremity has extensive skin loss and there is much loss of plasma early grafting may be the only means of restoring protein balance. Skin grafting of stumps for other than this reason is rather useless surgery. If for any reason skin grafts are to be used the donor site should not be any place on the extremity which is expected to use a prosthesis as too often painful irritable keloids result at the donor site which later interfere with the wearing of a prosthesis.

END-BEARING STUMPS

There is considerable disagreement in opinion regarding the ideal thigh stump. These differences of opinion are almost on the basis of nationalism. The British take the stand that no amputation stump is suitable for bearing weight on its end, and that end-bearing stumps will not stand up over a long period of time. They fit all lower limb prostheses even for a below the knee amputation so that weight is borne on the ischial tuberosity.

The general consensus of American surgeons is that an end-bearing thigh stump is

the best thigh stump possible. Certain Canadian surgeons are staunch advocates of end-bearing stumps and are great enthusiasts about the Griggs Stokes thigh amputation in which the patella is attached to the sectioned femur for the weight-bearing end. They are also great champions of the Syme amputation, an end-bearing tibial stump. The British quite stalwartly condemn both the Griggs Stokes and the Syme amputation.

Our experience makes us feel that an end-bearing thigh stump is the desirable type of thigh amputation to obtain when possible in an individual under forty. We have seen this type stump stand up under the most vigorous usage that can be given them and we feel that the patient walks with a more secure and better gait. We are not greatly enthusiastic about the Griggs Stokes type of end-bearing stump. The reason for this is that despite the best of technique in carrying out the operation the patella will in a certain number of instances, slide off the end of the femur resulting in an unsatisfactory stump. Its scope of application is also very restricted. Where there is any chance of even the mildest sepsis, complications are likely to be very time consuming. It is an osteoplastic operation, which to be successful requires the patella to unite by bone to the end of the femur just as any fracture heals. Even a mild infection may result in a failure of union of the patella to the femur or in an osteomyelitis of both the patella and femur. Because of potentially infected tissue the Griggs-Stokes type of amputation is not often applicable to the re-

amputation or closure of open amputations that have been done for trauma. In addition the tendoplastic type of end bearing thigh stump in which the patella is removed and the quadriceps tendon turned over the end of the femur produces an end bearing thigh stump which is just as good as the Gritti Stokes stump (Figs 10 and 11).

The Syme amputation has never been very popular in this country. It has had a lukewarm reception for the following reasons. Until the last few years it has been difficult to obtain a satisfactory prosthesis for this stump and American leg makers were not interested in supplying one. The Canadian limb makers have developed an excellent prosthesis for the Syme stump which is now universally available in the United States. Being unfamiliar with this operation American surgeons have had too many failures due to necrosis of the skin flaps and to a misalignment of the heel pad.

The operative technique and the post operative care of this stump are more exacting than in any type of amputation. The blood supply of the heel flap comes almost completely from the medial side through a branch of the posterior tibial artery. If the operation is done from the inside out by disarticulating the ankle through the anterior portion of the incision and the os calcis is removed sub

periosteally the blood supply to the heel flap is never endangered and the chances of skin necrosis are obviated. If the foot is removed from the outside inward and the skin fat flap of the heel is taken off the os calcis extra

perosteally the blood supply of the flap will be cut off in a considerable number of instances.

There is a tendency for the heel flap to slide to the inside of the stump or to assume a varus position so that the pad of the heel is to the end of the tibia, like a side car on a motor cycle, and this, of course produces a useless stump. This sliding of the heel flap is very easily avoided by maintaining it in place over the end of the tibia with adhesive straps which are changed at intervals for a period of 4 weeks. At the end of this time the pad is well stuck to the tibia and there is no further danger of medial displacement.

For a male the Syme amputation is the best possible amputation stump in the lower limb. It has the advantage that the prosthesis does not extend above the knee. In the prosthesis the patient can walk and stand longer than with any other type of leg amputation and it is possible for a patient to walk with a gait that is so close to the normal that the public will not know he is an amputee. In addition to these facts even without the prosthesis the patient need not use crutches or hop. Because of the length of the stump and because it is end bearing he can walk about the house at night on the end of the stump or when swimming or golfing he can get around to the shower and bath without having to carry crutches with him (Figs 12 to 19).

The Syme amputation is not a good amputation for a woman. The prosthesis for this

amputation is bulky and unsightly at the ankle. From a cosmetic viewpoint, it is probable that women would not be happy with this type of amputation despite its superiority of function.

The British objection that this amputation will not stand wear and tear is without foundation. In Toronto there are many patients with a Syme stump who have been at work on the stump every day during the 25 years which have elapsed between wars. We have also used this type of amputation in some 60 patients and they are doing well. It has been used whenever possible in all Army Amputation Centers during the present war and the American surgeon will become more acquainted with its value.

AMPUTATIONS THROUGH FOOT

Many types of amputation preserving the tarsal bones are described among which is the Chopart amputation. These types of amputations are frequently tried because of the fact that they preserve the ankle joint. The Chopart amputation is doomed to failure and should not be done if the muscles on the front of the leg have lost their attachment to the stump of the foot. This is simple to determine. If these muscles have an attachment to the foot the patient can dorsiflex the foot stump. When the attachment of these muscles to the tarsus can be preserved the Chopart or any amputation through the foot should be done in preference to a higher amputation as the

Fig. 22. Arm amputation stumps of no functional value. (a) Described in text. (b) Through surgical neck of humerus. (c) At pectoral insertion. (Courtesy of J. B. S. G.)

individual will be less handicapped. This of course does not apply to amputations done for arterial disease.

In instances where the anterior muscle attachments to the foot the anterior tibial cannot be preserved the foot stump will gradually and inevitably assume a fixed equinus position due to the unopposed action of the gastrocnemius soleus muscle group and the foot stump in this position will be a handicap rather than a benefit. In instances where this muscle imbalance cannot be prevented a Syme amputation is preferable to the deformed remains of the foot (Fig. 20).

SHORT BELOW KNEE STUMP

A question which often faces the surgeon is how short a below the knee stump is useful and should be preserved. Or to put it another way, How much of the leg must remain before an amputation is done through the femur and the knee discarded? A good rule to follow is that any length of stump which can be seen to project when the knee is flexed should be saved. A stump which projects as little as 1 inch with the knee flexed is of value to the patient as a motor for moving the prosthesis through the normal knee. Although a patient with such an abbreviated below the knee stump will have to wear the same type of prosthesis as an above the knee amputee, he will use the prosthesis better and will have greater security and control in going down

incline. A patient with a stump which projects 2 inches below the thigh when the knee is flexed will be able to do well with the ordinary below the knee prosthesis and will not need an ischial bearing prosthesis. An occasional leg maker will depreciate these short below the knee stump because they are difficult to fit, but the knee should never be sacrificed in an individual who has good circulation if the stump can be seen to project when the tibia is flexed to a right angle on the femur (Fig. 21).

UPPER EXTREMITY AMPUTATIONS

Amputations of the upper extremity are not common in civilian practice and it is therefore rare that a civilian surgeon has much experience in dealing with the problems of these individuals. The general attitude of surgeons toward amputations of the arm is

Fig. 23. Photograph of stenture harness required to keep prosthesis in place on amputation from just below the shoulder. (Courtesy of J. B. S. G.)

Fig. 24.

b

Fig. 25

to save all possible. This is a good attitude but it can be elaborated a little further as some arm stumps are more satisfactory than others.

No amputation through the humerus above the level of the humeral insertion of the pectoralis major produces a stump which has any functional value worthy of consideration. This fact does not mean that the head of the humerus should be removed unnecessarily as it tends to round out the shoulder and from a cosmetic viewpoint is desirable. Even though an inch or two of the humerus remains, if the pectoral attachment has been lost the end of the short piece of bone is pulled by the rotators into abduction and forward flexion. Amputations just below the pectoral attachment also produce stumps of little value in motivating a prosthesis. At this level the remainder of the humerus stays opposed to the thoracic wall and just a little forward and backward motion of the stump is possible. This movement is practically valueless in using an artificial arm. To maintain a prosthesis in place on these high amputations, an elaborate uncomfortable harness is necessary. Because of the uncomfortable harness, the weight of the prosthesis, and the uselessness of the artificial extremity most patients ultimately discard the mechanical extremity and go about with an empty coat sleeve (Figs. 22 and 23).

The best site for an amputation through the humerus to secure the bone length adapted to the most efficient use of a prosthesis is the level just above the beginning of the flare of the condyles of the humerus. At this site 2 to 3 inches of bone above the elbow are removed. Amputation here is superior to a disarticulation through the elbow as it allows room for the mechanism of the elbow block, without placing the elbow at a lower level than the remaining arm and thus making a disproportionate forearm. The absence of the condyles and the loss of the distal 2 to 3 inches of the humerus do not detract enough from the functional value of the humeral lever to offset the cosmetic and mechanical difficulties in the prosthesis (Fig. 24).

The importance of saving the elbow joint when possible cannot be too greatly stressed. The functional value of the elbow to the upper extremity is even greater than that of the knee to the lower extremity. Without an elbow joint under voluntary control, the arm amputee is limited to a few positions of the forearm, under the control of a mechanical lock which he must unlock with the other hand to release. In close quarters, even with the ideal humeral stump he may have to place the forearm of the prosthesis in one of a few positions available with the other hand. Even a relatively short stump of the forearm

will obviate this difficulty to a large degree. The short stump of the forearm need contain only a piece of the ulna and the necessity for removing the proximal end of the radius does not interfere with active flexion of the elbow since the brachialis muscle attaches to the ulna. An elbow joint is of great value even though it does not have total motion. A flail elbow joint is also of value. The condition of the humerus above the joint does not have to be normal to make the elbow worth saving. As the arm is not a weight bearing extremity a fibrous union of the humerus may suffice for excellent use of the forearm stump since the corset of the prosthesis will stabilize the humerus, as the sidebars will stabilize a flail joint at the elbow. No unnecessary reconstruction which through long immobilization might lead to stiffness of the elbow should be proposed when it will jeopardize function (Figs. 25 and 26).

The ideal forearm stump is one through the junction of the middle and lower thirds of the forearm. This level provides enough bone length for a firm grip on the cuff of the prosthesis by the stump and permits 2 to 3 inches of the volar surface of the forearm below the elbow to be unencumbered by the prosthesis cuff. This eliminates interference with flexion of the elbow caused by the cuff pinching and impinging on the front of the arm. This level is also just above the site at which the forearm becomes largely tendinous and avascular. Such a stump has an excellent blood supply, is warm and will tolerate well the rubbing of a prosthesis cuff. Forearm stumps shorter than this are very useful but, as the distance between the end of the stump and the insertion of the biceps decreases the necessity for covering a greater proportion of the volar surface is increased and flexion of the elbow may be interfered with by the encasement of the prosthesis. In the lower third of the forearm after the muscles have merged with their tendons there is poor circulation as only main arteries traverse this area. Stumps through this area are cold and often cyanotic. Ulceration of skin is not uncommon in stumps in the lower third. The difference in temperature at these two levels can be easily detected by palpation with the hand.

Fig. 25. Short one bone (ulna) below elbow stump.
Fig. 26. Short one bone (ulna) below elbow stump.

Disarticulation through the wrist joint is not a lack of amputation. It has all the disadvantages of a stump in the lower third of the forearm. In addition the inferior radioulnar joint may be very painful on pronation and supination. The loss of its carpal articulation and abutment causes a loss of stability of the joint which produces pain. The prominent ulnar styloid processes represent a major liability in the prosthesis and the stump is likely to be sensitive.

The stump which contains the proximal or proximal and middle wrist carpal bones is however a very useful and satisfactory stump from the functional viewpoint. From the cosmetic aspect it has a few disadvantages. The reason for the superiority of this stump to the disarticulation through the wrist are obvious. First of all it must of necessity be covered by tissue with a good blood supply—as the palmar flap of the heel and upper half of the hand. Second the inferior radioulnar joint is stable and painless because of the presence of its normal abutments and ligamentous support. Third there are no bony unprodded prominences. The length of the stump containing carpal bones together with the slight voluntary flexibility of this distal end make it of considerable aid to the patient without a prosthesis. This stump can be used satisfactorily for a stabilizer in such activities as driving a car, tying shoe laces, tying a necktie, buttoning a coat, etcetera. This stump also requires much less harness to keep the prosthesis in place and to motivate it powerfully (Figs. 27 to 31).

a

b

Fig. 25. Prosthesis for an above elbow stump. Dark triangular area contains lock which patient must manipulate with other hand to obtain different degrees of flexion and extension. (Courtesy *J Bone Surg*)

to save all possible. This is a good attitude but it can be elaborated a little further as some arm stumps are more satisfactory than others.

No amputation through the humerus above the level of the humeral insertion of the pectoralis major produces a stump which has any functional value worthy of consideration. This fact does not mean that the head of the humerus should be removed unnecessarily as it tends to round out the shoulder and from a cosmetic viewpoint is desirable. Even though an inch or two of the humerus remains, if the pectoral attachment has been lost the end of the short piece of bone is pulled by the rotators into abduction and forward flexion. Amputations just below the pectoral attachment also produce stumps of little value in motivating a prosthesis. At this level the remainder of the humerus stays opposed to the thoracic wall and just a little forward and backward motion of the stump is possible; this movement is practically valueless in using an artificial arm. To maintain a prosthesis in place on these high amputations an elaborate uncomfortable harness is necessary. Because of the uncomfortable harness the weight of the prosthesis and the uselessness of the artificial extremity most patients ultimately discard the mechanical extremity and go about with an empty coat sleeve (Figs. 22 and 23).

The best site for an amputation through the humerus to secure the bone length adapted to the most efficient use of a prosthesis is the level just above the beginning of the flare of the condyles of the humerus. At this site 2 to 3 inches of bone above the elbow are removed. Amputation here is superior to a disarticulation through the elbow as it allows room for the mechanism of the elbow block without placing the elbow at a lower level than the remaining arm and thus making a disproportionate forearm. The absence of the condyles and the loss of the distal 2 to 3 inches of the humerus do not detract enough from the functional value of the humeral lever to offset the cosmetic and mechanical difficulties in the prosthesis (Fig. 24).

The importance of saving the elbow joint when possible cannot be too greatly stressed. The functional value of the elbow to the upper extremity is even greater than that of the knee to the lower extremity. Without an elbow joint under voluntary control, the arm amputee is limited to a few positions of the forearm under the control of a mechanical lock, which he must unlock with the other hand to release. In close quarters, even with the ideal humeral stump he may have to place the forearm of the prosthesis in one of a few positions available with the other hand. Even a relatively short stump of the forearm

simple surgical procedure that is not mutilating and it would seem that in certain well selected patients its trial might be justifiable. The skin tunnels can be easily removed with out detracting in any way from the previous value of the stump if they are found unsatisfactory.

PHYSICAL THERAPY IN POSTOPERATIVE CARE

Physical therapy has a definite rôle in the postoperative treatment of the patient who has lost part of an extremity, and this rôle is too often not clearly enough understood by the surgeon. Massage has very little place in returning the stump to its optimum condition. Its only use is to free an adherent scar. Its efficacy in shrinking a stump is of little value and is far surpassed by the use of elastic bandages, properly applied and by the use of a temporary walking prosthesis such as a pylon. The real shrinkage of the stump takes place with activity and weight bearing, and may be so rapid as to make a new leg a profit in a few weeks. Shrinkage should be accounted for to a large degree before the permanent prosthesis is obtained.

The real value of physical medicine in the care of the amputee is in (1) the prevention and relief of contractures and (2) the development of the muscles which will later be used in motivating the prosthesis.

It is a very common thing for an amputee to develop a contracture of a joint in the involved extremity during the preoperative and immediate postoperative period. The joints most commonly involved in the lower extremity are the hip and the knee and in the upper extremity the shoulder.

The flexion contracture of the hip is the most serious detriment to the proper use of a

Fig. 31. Prostheses for forearm stump with carpal bones. a, Left. Light harness. b, Powerful control split hook in position. (Courtesy J. Bone Surg.)

prosthesis and is most frequently overlooked. The contracture is due to a shortening of the lateral or abductor muscles of the thigh. With the stump abducted it is not obvious; with the stump adducted it may be very prominent. The deformity makes it necessary for the patient in standing either to bend forward and thus submit to gravity or to arch his back to compensate for the flexion in order that he may hold his head over his feet. The compensation by increasing the lordosis leads to backache and to early arthritic changes in the spine.

The fitting of a prosthesis to an abducted or flexed stump is difficult and the deformity must be compensated for. It is this deformity in the thigh stump which leads to the bucket striking the adductors and pubis and causing great discomfort. In very short thigh stumps the flexion-abduction contracture cannot be obviated and the bucket must be especially constructed to accommodate for it.

In all thigh stumps which preserve half the length of the leg this contracture can be re-

Fig. 32. Cosmetic latex hand on long carpal bone stump. a, Left, Caucasian, cosmetic prosthetic hand on right hand. b, Negro, cosmetic prosthetic hand on left hand. (Courtesy J. Bone Surg.)

ieved by stretching exercises and the development of muscles which prevent it. The development of these contractures can also be obviated by the simple expedient of having the patient lie periodically on the stomach instead of sitting in bed with the hip flexed or propped up on pillows for 24 hours a day.

Flexion contractures of the knee occur frequently in below the knee amputations and when present to over 10 degrees are a serious impediment to walking as the partially flexed knee lets the patient down. They are best prevented and this is easily done by having the patient contract the patella, straightening the knee which also helps to prevent atrophy of the quadriceps muscle. When present they usually yield readily to passive stretching of the hamstring muscles and the capsular structures.

In the upper extremity the frozen shoulder with the humerus bound to the side, is easily prevented by keeping the amputated extremity on an aeroplane splint in 90 degrees of abduction. This is also a very great adjuvant to healing as it obviates the dependent edema and bogginess in the tissues. A contracture of the shoulder will yield just as any adhesive bursitis to passive stretching of the contracted pectoral muscle and active exercise of the deltoid and rotators. No amputated extremity can be expected to use a prosthesis efficiently until all contractures are released.

The efficient use of an artificial leg in an above the knee amputee depends on the full development of the gluteus maximus muscle which extends the hip and the adductor muscles which pull the leg toward the midline. Too often after the invalidism which has accompanied the surgery these muscles are atrophied and weak. Special exercises against resistance to strengthen these muscle groups should be instituted as soon as the stump is healed from surgery. It does not take a masseuse to carry these out and the surgeon who removes the leg should instruct the patient in them and see that he carries them out to the point of good muscular development otherwise he has completed his job no more than has the surgeon who removes an eye and leaves an unsuitable socket for the artificial eye.

The patient with a below the knee stump, in addition to having good musculature to extend and adduct the hip must have good muscles to extend the knee. Exercises to develop the quadriceps femoris should be started early and continued until there is good strength in this muscle group.

The arm amputee must have a good deltoid and if he has an elbow joint must have a good biceps to flex the prosthesis.

SUMMARY

1. The open circular or guillotine amputation is the safest type of procedure in the presence of infection. Proper after-care consisting of skin traction is a requisite to a good result in this type operation. A late secondary operation is necessary as a final procedure. This combination results in a better tailored stump than the open flap type of operation.

2. Fascia and skin or skin alone should be the only covering of an amputation stump. No muscle should be turned over the end of the stump. Aperiosteal technique is neither necessary nor sound. The nerve end should be well recessed under muscle. No chemical treatment of the nerve end is necessary. Complete hemostasis is necessary to good result.

3. Phantom limb is commonplace after amputation. Painful phantom limb syndrome is another thing. Drugs, alcohol, and psychic factors play a great part in the production of the latter. Surgical removal of neuromas does not benefit the established 'painful phantom limb syndrome' and any surgical attack on the syndrome will in almost all instances result not only in failure to cure but aggravation of symptoms.

4. Pedicle grafts are not satisfactory for weight bearing stumps and will not stand the wear of a prosthesis. Skin grafting of open amputations is not necessary if proper after care consisting of traction, is carried out. Skin grafting does not facilitate final surgery.

5. End bearing stumps are desirable in individuals under 40 years. They will stand up over time. The tendoplasty thigh stump is the best end bearing thigh stump. The Syme amputation is the best possible stump in the lower extremity if the foot must be sacrificed.

6 A below the knee stump which projects as little as 1 inch when the knee is flexed should be saved. It is of great help in motivating a prosthesis.

7 Any partial foot stump which has the anterior muscle groups attached should be saved. If the anterior muscle group is not attached a partial foot stump will inevitably go into severe equinus deformity and a Syme amputation is superior.

8 A humeral stump at or above insertion of the pectoralis major has no functional value. Every effort should be made to save the elbow joint even though the stump below

it is very short. Long stumps with the carpal bones in are excellent. Disarticulation through the wrist leaves a poor stump. The best site for forearm amputation is the junction of middle and lower third.

9 Indications for cineplasty are extremely restricted. It should not be considered except in bilateral upper extremity amputees.

10 Physical therapy has a definite place in the preoperative and postoperative care of amputees. Massage is of very little value. The function of physical therapy is to prevent and release joint contractures, and to develop musculature.

CANCER OF THE CERVIX

A New Technique for Interstitial Implantation of Radium into the Parametrium

E. EUGENE COVINGTON M.D., Baltimore, Maryland

A NEW technique has been developed for interstitial implantation of radium into the parametrium and lymph nodes of the pelvis in cancer of the cervix. This is a preliminary report on the first 100 cases. It is not an analysis of 5 year results as some of the patients have been treated less than 5 years. The patients treated so far have all been clinical stages I (3 cases), II (17 cases) and III (80 cases). Interstitial therapy is not justified in stage IV cancer of the cervix.

REASONS FOR A NEW TYPE OF RADIOTHERAPY

The new technique was developed for several reasons chief of which are as follows

1 *Inverse square law* The inability to deliver enough irradiation into the parametrium and lymph nodes of the pelvis by the usual course of roentgen therapy combined with contracervical and intrauterine applications of radium. It should be emphasized that the loss of irradiation due to the inverse square law makes it impossible to concentrate a lethal (10 to 12 erythemas) dose of irradiation into the parametrium and lymph nodes along the lateral wall of the pelvis by the usual contracervical and intrauterine applications of radium. For example, if the true pelvis measures 12 centimeters in its transverse diameter the center of the pelvis (intrauterine canal) is 6 centimeters from the lateral wall. Due to the inverse square law it would take 36 times as much radium (3600 mgm. hrs. of radium) in the cervix to get 100 milligram hours of radium into the lymph nodes along the lateral wall of the pelvis. This amount would be 1 erythema or about one-tenth the amount of irradiation necessary to destroy

cancer cells present in the lymph nodes along the lateral wall of the pelvis. It is thus obvious that some form of interstitial therapy is necessary to concentrate a lethal dose of radium into the parametrium and lymph nodes along the lateral wall of the pelvis.

2 *Local recurrences in the cervix* There have been too many recurrences locally in the cervix and adjacent parametria following the usual amount of irradiation. In numerous clinics an average course of irradiation therapy is about as follows: 2000 r to each of four pelvic fields followed by one application of contracervical and intrauterine radium (3000 to 4500 mgm. hrs. of radium). The author has seen too many positive biopsies after this form of therapy. A two dose technique of radium application, the last being interstitial, is now advocated: thus a greater amount of irradiation can be delivered to the cervix and a much greater amount to the parametria and lymph nodes of the pelvis. Pathologists have observed from autopsy studies a high percentage of deaths from cancer of the cervix with the tumor still localized to the pelvis and no evidence of generalized metastases. About one-third (reports of clinics vary from 20 to 35 per cent) of all deaths from cancer of the cervix are due to urinary obstruction from extension of the tumor into the parametria. Morton noted that almost 50 per cent of the cases of cancer of the cervix had microscopic cancer cells present in the cervix at the time of operation. This high percentage of residual cancer after radium treatment is not general throughout the country but it does strengthen the argument that there are still too many cases in which the cancer still localized to the cervix, has not been eradicated by radium. Taussig and Meigs have found positive glands in the pelvic lymph nodes at operation in

From the Departments of Radiology of Mercy St. Joseph's, and St. Agnes' Hospitals.

almost one-third of all early cases (stages I and II) when they were not suspected clinically before operation. Many observers Teahan, Pomeroy, Pitts and Waterman and Arneson dissatisfied with their results in cancer of the cervix with parametrial extension are advocates of interstitial implantation of radium element needles or radon seeds into the parametrium through the vaginal route. It is thus obvious that interstitial therapy is necessary and must accomplish two purposes, a higher total dose of irradiation to the cervix, and a more equal distribution throughout the parametria and lymph nodes of the pelvis of a lethal dose of irradiation.

3 *Trend back to surgery* Within recent years there has been a renewed interest in the Wertheim type of panhysterectomy usually associated with the Taussig type of lymph node dissection for selected cases of early (stages I and II) cancer of the cervix. Many gynecologists now believe the combination of irradiation followed by panhysterectomy will give a higher percentage of 5 year cures than either procedure alone. It is certainly true that a panhysterectomy is a much safer surgical procedure after the gross tumor has been almost entirely destroyed and the secondary infection cleared up by previous irradiation therapy.

Surgeons have three good reasons for their belief in a radical type of panhysterectomy for cancer of the cervix. (1) There are still a few cases in which the cancer of the cervix cannot be controlled by the present-day type of irradiation. (2) About one third (Taussig 33.3 per cent, and Meigs, 17 per cent) of all early cases (stages I and II) will have cancer cells in the pelvic lymph nodes at operation. Irradiation has a delaying effect on such cancers, but a low 5 year cure rate. (3) Improvements in surgical technique especially the modern advances in the control of infections, have so lowered the operative mortality and morbidity that panhysterectomy is a safer procedure than in former years. Panhysterectomy then should offer a better 5 year cure rate in early cases, and it is now up to the radiologists to offer something equal to this definite step for ward obviating the necessity of resorting to major surgery.

TECHNIQUE OF RADIOTHERAPY

The author advocates a new technique for delivering a greater dose of irradiation to the cervix and a much greater dose equally distributed throughout the parametria and lymph nodes along the lateral wall of the pelvis.

First radium treatment As the first treatment 3600 milligram hours of radium with 1 millimeter platinum as a filter was used as follows. One long rubber tandem (90 mgm of radium \times 24 hrs. = 2160 mgm. hrs. of radium) was inserted into the intrauterine canal and a rubber tandem (30 mgm of radium \times 24 hrs. = 720 mgm. hrs. of radium) was packed with gauze as far laterally as possible into either lateral vaginal fornix. This procedure gave a fairly equal distribution of irradiation throughout the pelvis. A serious mistake and probably the most common cause of radiation necrosis is to concentrate a large quantity of radium in a small area usually the contracervical region giving an overdosage and thus necrosis in that small area and not enough throughout the pelvis. Packing the rubber tandems in the vaginal fornices with gauze is better than colpostat technique. There are so many anatomical variations and variations in the amount of cancer present that in many instances the colpostat technique was impractical. Five grams of sulfanilamide was routinely dusted on the cervix before the gauze packing. In the present day of sulfonamides and penicillin to control infections there is no reason to use roentgen therapy first for this purpose.

Roentgen therapy Within a few days (usually 1 to 7) after the first radium treatment roentgen therapy was started which was as follows. 2000 to 2400 r was given to each of four pelvic fields over a period of 4 weeks. The physical factors were 400 kilovolts, Thoreus filter (1.75 mm sn 8 mm. cu and 1 mm. al) 50 centimeters distance, and 15 centimeter cone portals. This technique gave a 42 per cent depth dose (42 per cent of 8000 r = 3360 r in the tumor) into the cervix (10 cm. depth) and adjacent parametria.

New interstitial radium technique As soon as the roentgen therapy was completed (usually 30 to 35 days after the first radium

treatment) the second treatment or interstitial implantation of radium was done. By this time the secondary infection was usually cleared up and most of the gross tumor especially the friable type of cauliflower growth, was almost entirely gone. A search of the literature reveals that no one has used exactly the same interstitial technique of radium as will now be described in detail as the author's technique. Four small incisions (5 cm.) were made in the vaginal mucosa at equidistant points as far laterally from the cervix (usually 2 to 3 cm.) as possible. The incisions were actually in the 2, 4, 8, and 10 o'clock positions around the cervix (Figs. 1, 2, and 3). It should be emphasized that the cutting was only through the vaginal mucosa and not into the parametria. A long Kelly clamp was next used to dissect a long tract (usually 2 to 4 cm.) into the parametrium through each of the four incisions. This dissection is the most dangerous part of the whole procedure but by care, patience and experience the author has now done this new procedure in well over 100 patients with no evidence of injury at operation to a blood vessel, ureter, bladder or rectum in a single case.¹ After dissection of the four tracts as described, four rubber tandems were made up as follows: two tandems contained 25 milligrams of radium, and two tandems contained 20 milligrams of radium (usually 2 tubes of 10 mgm. each). A rubber tandem was then inserted into each of the four tracts. This gave 1260 milligram hours of radium (45 mgm. of radium \times 28 hrs. = 1260 mgm. hrs. of radium) into either parametrium or a total of 2520 milligram hours of interstitial radium. A long rubber tandem (60 mgm. of radium \times 28 hrs. = 1680 mgm. hrs. of radium) was then inserted into the intrauterine canal. Five grams of sulfanilamide was routinely used locally and the vagina was packed with gauze. The gauze packing helps to push the bladder and

rectum forward and backward respectively away from the radium.

TOTAL RADIATION GIVEN

A glance now at Table I will show that irradiation given over a period of 35 to 40 days, by use of a two dose radium technique, the last being an interstitial application, combined with roentgen therapy as described accomplished two purposes: a high total dose given to the cervix (3360 mgm. hrs. of radium + 3360 r.—42 per cent of 8000 r.—of roentgen therapy) and a high total dose fairly evenly distributed throughout the parametria and lymph nodes of the pelvis (1980 mgm. hrs. of radium + 3360 r. of roentgen therapy to either parametrium). The total irradiation given directly into the tumor is thus 7800 milligram hours of radium + 3360 r. of roentgen therapy.

CONTRAINDICATIONS FOR INTERSTITIAL RADIUM THERAPY

Interstitial implantation of radium was always discontinued for any of the following three conditions:

1. *Radiation fibrosis.* There was an occasional patient, most commonly an elderly woman who would develop so much fibrosis from the first radium treatment and the 8000 r. of roentgen therapy previously given that the

¹This new dissection and implantation of radium technique was done several times in the autopsy room on fresh cadavers before attempting it on patients. The dissection of the tracts was done by the manner described and dummy radium tandems were implanted. The tractions were exposed and the locations of the 4 tandems were observed in their anatomical relations to the ureters, the blood vessels, bladder, rectum, and parametria, and their distances from the cervix and lateral wall of the pelvis were measured. The tandems were usually 1 to 2 centimeters lateral to the cervix, medial to the big blood vessels, and lateral to the ureters.

Fig 1

Fig 1. Photograph of the actual radium tandems used for this series of 100 cases. There are 4 rubber tandems (2 contain a 25 mm. tube of radium and 2 contain a 30 mm. or a 35 mm. tubes of radium) for interstitial implantation into the 4 carefully dissected tracts of the parametria and a long rubber tandem (either 30 mm. tubes or a 35 mm. tubes of radium) for intrauterine application. The tandems are made of Dakin's tubes (2 mm. of rubber) with strong silk strings attached. The filter is thus 1 millimeter platinum, 3 millimeter rubber. It will cause less necrosis than radon seeds (3 mm. gold filter).

Fig 2. Artist's drawing of implantation. Note the positions of the 4 tandems for interstitial implantation situated at equidistant points (2 to 3 cm. lateral to the cervix) at 2, 4, 8, and 10 o'clock positions. Note the absence of a contracervical application. The author believes they concentrate too large a dose of irradiation to the cervix and thus cause necrosis.

Fig 3. Photograph of a roentgenogram showing the locations of tandems and the long intrauterine tandem (the 2 large radium capsules centrally located). Note that the 2 tandems in either parametrium are about one-half the distance from the middle of the pelvis (intrauterine canal) to its lateral wall thus giving a wide and equal distribution of a lethal dose (1200 mmm. hrs. of radium) to either parametrium.

dissection was difficult and probably too dangerous. Interstitial therapy would surely cause more fibrosis and thus increase the possibility of late complications, i.e. urinary obstruction from stricture of the ureters, sciatic nerve pain from the pressure of scar tissue on the sciatic nerve plexus or stricture of the rectum.

2. **Infection.** An occasional patient, usually with the infiltrative type of lesion still had too much infection present following the

Fig 2

Fig 3

previous radiotherapy to justify the risk of dissection and parametrial implantation of radium. A persistence of infection was nearly always due to two causes (1) radiation necrosis from a previous overdosage of radium concentrated to a small area or (2) uncontrolled cancer. A combination of local infection and radiation necrosis was usually a sign of a bad prognosis.

3 *Advanced cancer* Many times examination under anesthesia would reveal a more advanced lesion than was thought present before operation. This has been a common error. Many of the cases, especially in the early days of development of the new technique called stage III we would now classify as stage IV. The personal equation and enthusiasm of different authors vary and thus the differences noted in the classifications of the clinical stages of cervical cancer.

ADVANTAGES OF INTERSTITIAL RADIUM THERAPY

The author claims the new technique of interstitial radium implantation into the parametria has the following advantages: (1) It eliminates the necessity for an abdominal operation. (2) Positive biopsies after treatment are less than was noticed by the older method of therapy; thus the 5 year cure rate should be higher. (3) It gives a more equal distribution and higher total dosage of irradiation in the parametria and lymph nodes of the pelvis. There have been only 4 cases (4 per cent) of death from urinary obstruction due to parametrial extension as contrasted with the 20 to 35 per cent as recorded in the literature. (4) The filter (1 mm pt. + 2 mm of rubber) causes less necrosis than radium needles or radon seeds. Radon seeds have a filter of 3 millimeter of gold which allows enough beta rays to pass through to cause necrosis adjacent to the seeds. (5) There is no danger of puncturing a blood vessel, ureter or bladder when the blunt rubber tandems are inserted into the four carefully dissected tracts. This is a serious danger when radium element needles or radon seeds are inserted blindly into the parametrium. (6) Radium element needles with silk strings attached will occasionally get hung in the tissues on attempted removal. Several

observers have had this embarrassing experience making operative removal necessary. This mishap has not occurred with the rubber tandems placed in the carefully dissected tracts.

COMPLICATIONS OF INTERSTITIAL RADIUM THERAPY

The possible complications of this new technique for interstitial implantation of radium into the parametria were both early and late.

Early complications The dangers or possible early complications from the operation were as follows: (1) damage to the ureters with extravasation of urine; (2) damage to a large blood vessel with hemorrhage; (3) opening the peritoneal cavity with peritonitis as a result; and (4) pelvic cellulitis through any one of the four openings into the parametria. In this first 100 patients treated by the new technique none of these possible mishaps have occurred. This fact alone convinces the author that the new technique is certainly a safe procedure and could be learned easily by any radiotherapist with surgical training. Cystitis, proctitis, irradiation sickness and erythema with desquamation of the skin around the pelvis were noted with about the same frequency with the new technique as was noted by older methods. They were at times troublesome and annoying to the patient but never serious.

Late complications The late complications from interstitial radium implantation were more serious than the early and were noted as follows: (1) A fairly severe proctitis was the most common late complication and was noted in 6 patients, 1 of whom developed a stricture severe enough to require colostomy. The other 5 patients still have occasional attacks of diarrhea with bloody mucus in the stools. Proctoscopic examination showed the typical picture of irradiation proctitis, usually most pronounced about 6 to 8 centimeters above the anus. All 6 of these patients are clinically free of cancer. (2) Rectovaginal fistulas have been produced in 4 patients, 3 of whom probably had stage IV cancer and should not have been treated by interstitial therapy. All 3 of these patients have necroses, fistulas, and still have positive biopsies after the heavy total dose of irradiation given in this series. The fourth patient is living and clinically free of

cancer over 5 years but she still has the fistula. The author considers this fistula was due to overirradiation. (3) Irradiation necrosis of the cervix was present in several cases, especially the late stage III (or IV²) cases in most of which cancer was still present locally in the cervix after treatment. One patient has developed late irradiation necrosis of the cervix several months after treatment and is still clinically free of cancer. (4) Urinary obstruction was the ultimate outcome in 4 patients each of whom had cancer clinically in the parametrium and in 2 cancer was proved by autopsy. This complication was studied carefully because interstitial radium therapy always produces more fibrosis than external irradiation. It is certainly safe to say that extension of cancer into the parametrium was several times more common as the cause of obstruction to the ureters than irradiation fibrosis. (5) Secondary vaginal hemorrhages were a serious complication in 7 cases. There was also 1 fatality from rectal hemorrhage. In every case of secondary hemorrhage the patient had uncontrolled cancer in the cervix.

Briefly to summarize the complications of interstitial irradiation there were no early complications from the implantation but there were 6 cases of irradiation proctitis, 1 case of rectovaginal fistula and 1 case of radiation necrosis of the cervix as late complications. All the remaining cases of fistulas, necroses, secondary hemorrhages, urinary obstructions and distant metastases were due to uncontrolled cancer and not to overirradiation.

RESULTS

The primary purpose of this paper was to show the necessity of interstitial radium therapy for cancer of the cervix and the advantages of a new technique used by the author in 100 cases. It is not a 5 year study as a few of the patients were cared for less than 5 years ago. Seventy-six patients (76 per cent) are still living and under observation and 24 patients (24 per cent) have died of cancer. The known causes of death were as follows: 3 patients had rectovaginal fistulas, 2 had bone metastases, 2 had pulmonary metastases, 4 died of urinary obstruction, 7 had secondary vaginal hemorrhages, and 1 died of rectal hemorrhage.

SUMMARY AND CONCLUSIONS

From a study of the 5 late complications of irradiation the causes of death in 24 patients and the high percentage of positive biopsies of lymph nodes of the pelvis found at operation by surgeons it should now be obvious that a higher total dose of irradiation should be given to the cervix and a much higher total dose equally distributed throughout the parametria and lymph nodes of the pelvis.

1. There were no early complications from the interstitial implantation of radium but there were 6 cases of irradiation proctitis, 1 case of rectovaginal fistula and 1 case of radiation necrosis of the cervix as late complications. The 24 deaths were the result of uncontrolled cancer of the cervix and adjacent parametrium.

The advantages and contraindications of the new type of interstitial therapy were discussed in detail. Emphasis was placed on the greater safety of this procedure over other forms of interstitial therapy.

The author has tried to accomplish the following: (1) To eliminate the necessity of a major radical procedure for early carcinoma of the cervix. (2) To improve the complete radiation of the growth in the cervix. There have been 176 positive biopsies after treatment thus the 5 year cure rate should be better. There have been only 4 deaths (4 per cent) from stage II cancer of the cervix and none from stage I. This rate is far better than was obtained by previous methods of radiotherapy. (3) To reduce the number of deaths from parametrial extension of cancer by giving a higher total dose of irradiation equally distributed throughout the pelvis. This has also been effected as only 4 deaths (4 per cent) were due to urinary obstruction contrasted with the usual 20 to 35 per cent recorded in the literature.

Fig. 1 Schematic representation of abnormality in case here reported. Upper end of the esophagus ends blindly. Lower end of esophagus communicates with posterior portion of lower part of the trachea. Superior segment of the esophagus is slightly dilated while the inferior one is quite small.

of saliva appeared in the baby's mouth and it was necessary on several occasions to suck these away in order to establish a satisfactory airway. On the second day of life a dilute formula was offered but the feedings were promptly regurgitated. All attempts at feeding were followed by respiratory difficulty and cyanosis. The infant was seen in consultation by Dr. Adelman and was referred to this hospital with a diagnosis of esophageal atresia.

Physical examination on entry showed a well developed and well nourished white male infant in no acute distress. Temperature was 99.2° degrees F, respirations 24, pulse 120. The color was good and there was no cyanosis at the moment. The skin had a slightly icteric tint which was regarded as a physiological jaundice. The head, eyes, ears, nose and throat were normal. The sides of the chest moved equally, there was no intercostal retraction. The percussion note was resonant over both lung fields. There were numerous fine, moist rales and coarse rhonchi throughout the entire chest, more marked at the right apex. The heart was not enlarged to percussion. The cardiac sounds were of good quality and the rhythm was regular. There was no murmur. The abdomen was slightly tympanitic, and was normal to palpation. The liver edge was felt just below the costal border. The genitalia, extremities and reflexes were normal. By rectal examination meconium was found on the examining finger.

Röntgenologic examination was made immediately after admission. Under the fluoroscope a No. 8 French urethral catheter was passed through the infant's nose and down into the esophagus. The catheter would not pass into the stomach since it met

some obstruction in the middle portion of the esophagus. Two cubic centimeters of lipiodol were now introduced through the catheter. A blind esophageal pouch (atresia) was demonstrated at the level of the 4th thoracic vertebra (Fig. 2). Fluoroscopy and film studies showed a considerable amount of gas scattered through the stomach and intestines indicating the existence of a fistula between the trachea and the lower segment of esophagus. There were patches of atelectasis and emphysema throughout both lung fields, the changes being most marked in the right upper lobe.

The infant was placed in an oxygen tent. The upper blind end of the esophagus was kept cleared out by an insulating catheter which was passed in through the nose and was connected to a Wangensteen suction apparatus. Intramuscular penicillin was started in doses of 3,000 units every 3 hours. Sodium sulfisiazine was given subcutaneously with 200 mg. of streptomycin and subsequent doses of 400 mg. of streptomycin. Parenteral fluids were administered in 100 cubic centimeters of 5 per cent albumin intravenously and 100 cubic centimeters of 10 per cent glucose in 0.47 per cent saline intravenously. After 52 hours of this therapy the infant had a tracheostomy performed from the left side. The tracheostomy seemed optimal for

ventilation. By R.I.C. under cyclopropane anesthesia with a tightly fitting face mask.

Fig. 2 Lateral roentgenogram, with baby in upright position. A catheter has been introduced into upper portion of the esophagus and a cubic centimeter of lipiodol has been instilled. This iodized oil outlines lowermost extent of the blind upper sac. Air in the stomach and intestines indicates that the trachea must communicate with the lower esophageal segment.

Fig. 3. Azygos vein divided, entrance to mediastinum provided. Mediastinal structures exposed.

the infant was placed in a prone position with the right shoulder elevated slightly (Fig. 3). A curved incision was made just inside the medial border of the right scapula running downward and outward around the angle of the scapula. The superficial muscles were divided and the scapula was reflected upward and laterally and the costal cage exposed. The erector spinae muscles were mobilized slightly toward the midline. Subperiosteal resection of the segments (about 3 cm long) of the 3rd, 4th and 5th ribs was now carried out. The bundles of intercostal muscles with their accompanying nerves and vessels

were divided. The pleura was then stripped forward by blunt dissection from the vertebral bodies and the azygos vein exposed. This vein was doubly ligated and divided. Dissection was continued until the mediastinal structures were adequately exposed. The upper blind pouch of the esophagus extended down to a point opposite the lower portion of the trachea. The lower segment of esophagus had a fistulous communication with the posterior surface of the trachea about $\frac{3}{4}$ inch above the carina (Fig. 4a). There was some thin areolar tissue between the two esophageal segments. The lower part of the

esophagus was now extensively mobilized as far down as the diaphragm though this was accomplished at considerable risk to its blood supply. The tracheo-esophageal fistula was ligated with No. 0000 silk close to the trachea and was then divided (Fig. 4b). A long slit was cut in the lower esophageal tube. The upper esophageal pouch was extensively freed from surrounding structures up to the base of the neck. The thinnest area of this pouch was on its anterior surface along which an opening was made. Stay sutures of No. 00000 silk were placed in the four quadrants of each esophageal end. The No. 8 urethral catheter in the nose and upper esophagus was now pushed downward by the anesthetist so that it could be threaded into the lower segment and into the stomach. The near ends of the stay sutures were first tied following which the far ends were tied and thus the walls of the esophagus were rolled inward at the anastomosis. Next 7 or 8 interrupted sutures were used to join and turn in the musculature between the stay sutures. An effort was made to establish an oblique type of union in the belief that this might have less tendency to subsequent stricture formation. In anticipation of this type of junction slits had been made in each segment and it was thought desirable to make each slit where the respective segment seemed thinnest. In each case this was on the anterior surface. Unfortunately this procedure necessitated rotating the lower segment through a twist of 180 degrees in order properly to appose its opened end to that of the upper pouch (however this twist has in no way interfered with the subsequent function of the esophagus). The mediastinum was thoroughly irrigated with saline soaked out, and then filled with 25,000 units of penicillin solution. A narrow strip of soft rubber drain was placed near the anastomosis and was led out through the inferior angle of the skin wound. The chest was repaired by joining the intercostal muscle bundles posteriorly closing the superficial muscle layers and then approximating the skin. Debridement of No. 00000 silk on traumatic needles was employed throughout the procedure for both the esophageal anastomosis and the wound closure. The infant stool the operation quite well.

Postoperative course. The baby was again placed in an oxygen tent which was discontinued in 24 hours. Four hours after operation breast milk was injected through the indwelling gastric tube and was increased in a few days to supply full caloric requirements. A transfusion was given after operation and on the following day. Clysers were continued for 4 days. The infant's pulse and general condition were extremely satisfactory throughout the postoperative period. The mediastinal drain was removed on the 5th day there having been a discharge of only a few cubic centimeters of thin, serous, sanguinous fluid. The wound was solidly healed at the time of removal of sutures 3 days later.

Since we were unwilling to attempt feedings by mouth at so early a date and since we did not care to leave the nasal tube in place for a longer period a

Stomach tube was inserted into the lower esophagus. At the time the baby was moved and gastric tube was inserted into the stomach. Latent breast milk was taken up with caution. Since all particles of milk were swallowed with uterine tube the lungs were increased rapidly in an untimely manner. Because of difficulty with the infant's glutition the gastric tube was left in place and the baby was discharged home on the 10th day weighing 7 1/2 lb and taking full breast milk. Mouth Sulfazolin was used for 1 week after the mediastinal operation. Mediastinal drainage continued for the whole period of hospitalization.

Since leaving the hospital the baby has had a most satisfactory course. The feeding has been taken easily and with facility. The infant has usually been kept in a room with fresh air but has taken longer. The child has gained a few pounds in the diet has not returned to a normal weight. At no time has there been any purulent discharge after the act of feeding. The respiratory system has been healthy and that has been a

Fig. 5. Photograph of back on 9th postoperative day. The wound healed without infection and without esophageal leakage.

Fig. 6. Photograph of patient 16 months of age showing excellent general status.

quickly through the esophagus. There has been some visible constriction at the site of anastomosis and the lumen of the esophagus above this level has been somewhat larger than the lumen below it. However dilatations of the esophagus were not done at any time during the first year of life. The child's general physical condition has been excellent (Fig. 6) and the weight gain has been most pleasing (Fig. 7).

At about 1 year of age the child began to have some difficulty with swallowing of solid food and was returned to the hospital for short periods in the 13th

14th, and 15th months of life at which time the esophagus was dilated respectively to No. 30 (French) No. 30 and No. 41. Following this last and more thorough stretching deglutition has been very satisfactory. When last seen at 20 months of age there was no hesitation in swallowing.

DISCUSSION

At least five methods of primary anastomosis have been successfully employed for repair of esophageal atresia. Each of these procedures has certain factors which recommend it as a valuable approach to the establishment of esophageal continuity in infants. Final evaluation of each method is not possible until larger series are available for study but it is fitting at this time to point out some of the apparent merits or drawbacks of the different forms of anastomosis.

Haight (2,3) has recommended a primary repair whereby the tiny and thin distal segment is telescoped for a short distance into the upper segment in such a way that the entire thickness of the wall of the lower segment is joined by interrupted sutures to the mucosa and the submucosal layers of the upper segment (Fig. 8a). The muscularis of the upper segment is then lapped over and attached by sutures to the muscularis and adventitial structures of the lower segment.

Fig. 7. Patient's weight chart for first half year of life indicating satisfactory gain.

Fig. 8. Schematic drawings of types of esophageal anastomoses. a, Method of Haight. b, Daniel's procedure. c, Humphrey's technique. d, Ladd's method, employing tension sutures to relieve strain on line of union. e, Operation here reported. Ends of multiple bite sutures are tied opposite ends of these sutures are then being tied to roll in ends of esophagus. Oblique anastomosis.

The outstanding advantage of this method would appear to be in the sleeve-like overlapping of the muscular layers which obviously should give a great deal of strength to the anastomotic repair. The greatest drawback with this method would probably be the difficulty of placing the first row of interrupted sutures since the distal segment is usually small quite friable and easily torn. Hence there is considerable chance for the sutures to cut through or pull out, particularly if the segments have to be drawn together under any great tension. Aside from any theoretical disadvantages of the method, Haight's experience to date shows that in 3 cases a brilliant result has been obtained the babies have not needed gastrostomies and each has been able to take feedings satisfactorily. In 2 patients a fistula developed through the back, but each has healed spontaneously. In another individual, a tracheo-esophageal fistula reopened. Hence in each of these latter 3 cases it is obvious that some portion of the union had broken down after operation. Nevertheless Haight's reports have shown more recoveries from direct anastomoses than has any other publication to date.¹

¹Since completion of this manuscript one of us (R. E. G.) has attempted several more operations for esophageal atresia by the Haight technique. One of these has survived and at the moment we feel that this is the best method yet devised for esophageal anastomosis in babies with esophageal atresia.

Daniel employed an ingenious method for the surgical union of the two segments in esophageal atresia. After freeing and opening the upper and lower ends a catheter was placed in the nose led down through the upper segment, and threaded through the lower segment into the stomach. This catheter was used for upward traction after the esophageal end was tied to it. Thus the lower part of the esophagus could be pulled inside of the upper segment, to which it was then anchored with a number of interrupted stitches joining the muscle layers (Fig. 8b). The chief disadvantage with this procedure would seem to be that the esophagus is completely obstructed until the encircling ligature breaks or until it cuts through the esophageal substance. During this period of total obstruction saliva can accumulate and possibly spill over into the larynx and trachea. Some of this difficulty might be obviated by very careful nursing care during the postoperative period, so that any accumulated fluid could be frequently sucked out of the mouth and pharynx. It must be pointed out that Daniel was able to overcome a defect in which there was a very long separation between the two esophageal segments. Whether or not such a method will be productive of a higher percentage of strictures at the anastomosis site is as

It is needless to emphasize that great delicacy must be employed in the performance of esophageal anastomosis in babies. The tissues particularly of the lower segment, are extremely fragile and are easily injured. Every effort should be made to handle them with utmost gentleness and to avoid squeezing them with hemostats, forceps, or other instruments. The stay type of suture advised by Ladd provides an admirable handle for traction and for manipulating the esophagus. When one of these stitches has been placed all subsequent sewing can be accomplished without grasping the esophagus with a metallic instrument. In the case here reported it seemed to us of considerable importance that the esophagus was not touched with forceps more than three or four times during the entire surgical procedure. To complete such tiny operations successfully it is necessary to have a few instruments of diminutive size. A small blunt periosteal elevator or a septum elevator-dissector is essential for stripping the parietal pleura from the thoracic cage and the mediastinal structures. Tissue forceps should be no more than 3 or 4 inches in length and should have delicate toothless points. Scissors may be curved or straight, but should be no more than 3 or 4 inches in length. Of prime consideration is the type of suture material and the needle upon which it is threaded. We believe that fine braided silk is superior to any other type of suture material. Size No 00000 has adequate strength and a very small caliber. When attached to a No 9 Dehnatell atraumatic needle, it makes a superb material for use in babies.

The choice of anesthetic agent must of course depend upon the circumstances in a given clinic. Local novocain infiltration has been frequently employed. Avertin plus novocain has been favorably commented upon in some instances either has been preferred. Various authors have condemned general anesthesia but we are convinced that it greatly facilitates the performance of the operation and need not be productive of shock or untoward reaction. In the case here reported and in other instances in this hospital cyclopropane has been the anesthetic of choice. It gives sufficient relaxation and

carries a high concentration of oxygen. When supplied through a tightly fitting face mask it can be given under positive pressure if by accident the parietal pleura should be pierced at any time the lung can be easily expanded. Our selection of cyclopropane has been dependent upon the availability of an expert anesthetist who has had wide experience with its use in babies. Where such conditions do not prevail local anesthesia would probably be safer.

Discussion has arisen concerning the advantages of leaving a small rubber tube in the reconstructed esophagus. In our case a No 8 French catheter was led through the nose, down through the esophagus and into the stomach—and kept there for 8 days. We considered it to have value as a semi rigid structure for keeping the segments of the esophagus in line. Furthermore it was enormously useful for feeding purposes during the immediate postoperative period. Conceivably an intubating catheter can produce pressure necrosis in the anastomotic area but we are inclined to minimize this danger. Previous experience indicates that some infants will tolerate a tiny rubber tube in the nose for protracted periods of time while others develop such a violent reaction to it that nasal stuffiness and accumulation of secretions greatly embarrass the baby's breathing. In short if a catheter is tolerated well it is probably a valuable therapeutic agent. If however too much reaction is set up in the nose or throat it is folly to keep a tube in place.

The use of a gastrostomy is likewise a moot point. In the present case gastrostomy was performed 8 days after the esophageal repair but it was kept open for only a week. This patient fared so well that possibly he could have survived without the gastric opening. In 3 of Haight's patients no gastrostomy was employed. In general it would seem to us that the establishment of a Stamm gastrostomy under local anesthesia can be such an innocuous procedure that it should be almost universally done a day or two after the esophageal repair. The intubating esophageal catheter could be omitted and all oral feedings could be withheld for several weeks in order

SURGERY GYNECOLOGY AND OBSTETRICS

SUMMARY

to allow the best possible esophageal healing. While this routine would obviously impose a gastrostomy on some patients who might have survived without it there would doubtless be improvement in overall results when employed in a series of cases.

Observations are reported upon a baby with congenital atresia of the esophagus and associated tracheo-esophageal fistula. Surgical correction was undertaken through a right, extrapleural mediastinotomy. The tracheo-esophageal fistula was closed and the two esophageal segments then joined by a long oblique anastomosis.

The baby was discharged from the hospital 19 days after operation. Esophageal dilations were not required during the ensuing year but were performed thereafter. The child is in excellent health at 20 months of age. The surgical method is one which can be employed only when the esophageal segments lie close to one another or when they can be adequately mobilized to allow satisfactory approximation. Under such circumstances, the technique merits further trial in future cases.

The necessity for esophageal dilatations and the frequency with which they must be repeated will depend upon the tightness of any existing stricture and the severity of the dysphagia. The size and the function of the esophageal canal can be observed by a swallow of barium (or lipiodol) and fluoroscopic examination. However we are convinced that esophageal dilatations should not be performed solely on the basis of any roentgenologic findings which suggest a constriction at the site of anastomosis. Indeed, the indications for dilatation should depend almost entirely upon the subjective symptoms which occur during the ingestion of feedings. One gains the impression that scar tissue (if not too great) at the site of an anastomosis may give trouble for a temporary period, but that the symptoms can become much less as the child grows older and the esophageal lumen becomes greater. In short the lesser degrees of stricture may be troublesome at first, but they do not necessarily imply that dilatations will be required indefinitely.

PANCREATIC HETEROTOPIA

Review of the Literature and Report of 41 Authenticated Surgical Cases, of Which 25 Were Clinically Significant

JORGE J DE CASTRO BARBOSA M D MALCOLM B DOCKERTY M.D., and
JOHN M WAUGH M.D., F.A.C.S., Rochester Minnesota

THE presence of pancreatic tissue in an aberrant location, without connection with the main pancreas can at the present time no longer be considered merely as a rare and casual post mortem discovery or as an unusual and interesting but incidental finding at operation. In view of the multiple surgical cases of clinical significance reported in the medical literature it is a condition that should be kept in mind, recognized, and taken into due consideration by the surgeon who operates on the gastrointestinal tract.

In the past 5 years there has been an increased interest, both of the clinician and of the surgeon in conditions referable to the pancreas. Much study has been done in various sectors in this field. Much of this work has been dedicated to the clinical study and surgical treatment of hypoglycemia and hyperinsulinism. There have been examples reported in which aberrant pancreatic tissue was the site of hyperfunctioning insulin-producing, benign or malignant neoplastic tissue. The presence of a functioning aberrant islet cell adenoma or adenocarcinoma can possibly explain the enigma of some cases of idiopathic or so-called spontaneous hypoglycemia, in which an exploration does not reveal the presence of any tumor in the main pancreas.

Aberrant pancreatic nodules have at certain times caused embarrassment to the surgeon. At other times far from being merely an incidental finding heterotopic pancreatic tissue has been known to be the

source of considerable trouble and to be the cause of serious conditions for which a major surgical procedure had to be instituted to obtain relief.

The collection of cases in the literature especially in the more recent years, has been illustrative and revealing. The reports however have all been accounts of isolated instances and no large group of cases has yet been presented from one single source. The largest series being that of Branch and Gross, who presented 24 cases in only 5 cases however was heterotopic pancreatic tissue encountered at operation and in only 4 was it causative of symptoms.

In an endeavor to make a substantial contribution to the casuistics of this subject we have attempted to make a detailed clinical and pathologic study of all the surgical cases of pancreatic heterotopia found in the records of the Mayo Clinic. There is a relatively large group of cases with clinical significance especially in the more recent years.

MATERIAL AND METHODS

We reviewed a series of 82 surgical cases. Twenty five of these were authentic cases (confirmed by microscopic examination) of pancreatic heterotopia in which the heterotopic pancreatic tissue was clinically significant, in that either it was found to be the only or main lesion for which the patient was taken to the operating room or it was one of the lesions contributing to the production of symptoms. These cases are summarized in Table I.

Sixteen cases of the series were authentic cases of pancreatic heterotopia in which the heterotopic pancreatic tissue was merely found incidentally at operation during the course of a surgical procedure performed for some other lesion.

Abridgment of thesis submitted by Dr. Barbosa to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of M.S. in Surgery. From the Division of Surgery Mayo Foundation, and the Section on Surgical Pathology and the Division of Surgery Mayo Clinic.

TABLE I—SUMMARY OF AUTHORS' 25 SURGICAL AUTHENTIC CASES OF PANCREATIC HETEROTOPIA WITH CLINICAL SIGNIFICANCE

Case Year Sex Age	Macroscopic and microscopic location of pancreatic heterotopia Histologic evidence of active function	Size of mass Pathologic change	Symptoms	Roentgenologic contributions	Operative Results
014 F 42	Lesser curvature and posterior wall of stomach. Submucosa and infiltrating muscle layers. No	3.5 x 1.5 cm. (vulvar). None	Ulcer history. Pain 16 hrs. p.d. Loss 5 lbs weight in 3 yr.	Ovoid tumor mass mid-portion of stomach. Malignant	Partial gastrectomy, posterior Polya. Good immediate results since operation in June, 1911
014 M 33	Greater curvature pro-pyloric region of stomach. Submucosa and between muscle bundles. No	5 cm. in diameter. None	Past history of ulcer symptoms	Filling defect 3 cm. in diameter near greater curvature just proximal to pylorus	Excision. Good immediate results since operation May 1944. Wally 1 mm p.
3 1911 M 44	Stomach posterior wall greater curvature ca. above pylorus. ?	3 mm. in diameter. Slight retraction of mucosa 2.5 cm. in diameter resembling diverticulum, superficial erosion	Recurrent epigastric pain periodically for 23 yrs. At present no relief with diet	Duodenal ulcer	Partial gastrectomy, posterior Polya. Grade 3 post-ileitis with multiple superficial erosions.
017 M 41	Greater curvature of stomach ca. proximal to pylorus. ?	cm. in diameter. None	R.U.O. pain worse immediately p.c. for 3 yrs. No relief with diet	Polyp cm. in diameter near greater curvature in antrum	Partial gastrectomy, posterior Polya. Well 3 yrs p.c.
1 013 M 24	Pylic end of stomach. Submucosa and infiltrating muscle short. No	erect cm. None	Epigastric distress—none	Polypoid lesion 2.5 cm. in diameter in pyloric segment of stomach	Partial gastrectomy, posterior Polya. Well 3 yrs p.c. Well 3 yrs p.c.
010 M 38	Posterior wall of stomach just above angle. Submucosa and infiltrating muscular short. Yes	2.5 cm. Multiple large cysts were grossly in mass, dilated ducts	Upper abdominal distress 3-4 yrs. p. With food, acids and alkalis (transmucosa relief but diet without result). 5 yrs. Loss 20 lbs. Past yr. episode of hemorrhage	Design tumor in stomach 3 cm. in diameter. Just above lesser curvature above angle. Lymphoma?	Caution excision of gastric wall containing tumor. General condition fair. Some epigastric distress weight normal 4 yrs. 5 mm p.c.
1 011 F 23	Posterior wall of stomach proximal to pylorus. Submucosa. Yes	4 mm. in diameter. None	Epigastric distress with nausea hrs. p.d. for 2-3 yrs.	Polyp cm. in diameter on posterior wall of pro-pyloric region of stomach	Partial gastrectomy, posterior Polya. Well 9 mm. p. Well 3 yrs p.c.
010 M 35	Serosal surface pyloric ring. Submucosa. Yes	1 cm. in diameter. None	Periodic epigastric distress with burning and acid relief 4 yrs. Loss 25 lbs. 13 lbs. in 4 mos	Annular lesion involving pylorus in pro-pyloric area with duodenal malignancy?	Partial gastrectomy, posterior Polya
010 M 30	Stomach, lesser curvature. Submucosa. ?	cm. in diameter. Abscess pericyst directly below circumference ulcer (1). Malignant change	Ulcer history 3-4 yrs. hematemesis, tarry stools	Perforating ulcer lesser curvature of stomach	Partial gastrectomy, posterior Polya. Died 37 mos. p.c.
013 M 43	Stomach, lesser curvature. Submucosa. Yes	cm. in diameter. Hemorrhage	Daily ulcer symptoms past 5 mos.	Duodenal ulcer. Ulcer lesser curvature of stomach	Partial gastrectomy, posterior Polya, partial duod. oc. by S&J. Satisfactory 6 mos p.
1 M 39	Duodenum. Infiltrating longitudinal muscular fibers. Yes	3 x 1.5 cm. None (overlying duodenal ulcer).	Epigastric pain, no relief with diet, 3 yrs. Hemorrhage. Loss 1 lb. 3 yrs.	Duodenal ulcer, large crater	Partial gastrectomy, posterior Polya
013 M 33	First portion duodenum. Submucosa, infiltrating circular muscular fibers. Yes	? None (duodenal diverticulum)	Erythema of bleeding duodenal ulcer. Secondary anastomosis	Duodenal ulcer	Partial gastrectomy, posterior Polya. 3 mos. p. Very well 3 yrs. 3 mos. p.c.
1 1930 F 31	Inferior border duodenum. 5 cm. from pylorus. Submucosa. Yes	5 cm. in diameter. None	Epigastric distress 3 1/2 yrs. Temporary relief with antacids, tarry stools	Negative stomach and duodenum. Gastrobladder partially functioning with stress	Bronchus, subdiaphragm. No ducts and pancreas normal. Excision of duodenal nodules. Well 3 yrs 4 mos p. Well 14 yrs p.
14 1911 M 38	Duodenum 5 cm. below pylorus. Submucosa and infiltrating longitudinal and circular muscular fibers. Yes	5 mm. in diameter. None	Ulcer type of distress 5 yrs. Loss 10 lbs. No relief with diet.	Duodenal ulcer	No evidence of ulcer. Excision of tumor with portion of pyloric antrum. Reconstruction of pyloric outlet. General 12 lbs. Well 5 mos 13 yrs p.c. Working hard

BARBOSA ET AL. PANCREATIC HETEROTOPIA

TABLE I.—SUMMARY OF AUTHORS 25 SURGICAL AUTHENTIC CASES OF PANCREATIC HETEROTOPIA WITH CLINICAL SIGNIFICANCE—Continued

Case Year Sex Age	Macroscopic and microscopic location of pancreatic heterotopia Histologic evidence of adrenal function	Size of mass Pathologic change	Symptoms	Radiologic examination	Operation Results
1 1913 F 6	Anterior wall duodenum just below pylorus. Sub- serosa No	1.5x0.8 cm. Necrosis	Epigastric distress with food relief 5-8 yrs	Pedunculated polyp ap- proximately 1.5 cm. first part duodenum greater curvature side	Excision of tumor with reconstruction of pyloric outlet. Well 15 yrs p.o.
16 1914 F 30	Duodenum 1.5 cm. below pylorus anteriorly	3x2.0 cm. Duodenal ulcer immediately above pancreatic heterotopia.	R.L.Q. pain 1 yr		Excision of duodenal ulcer with node of pancreatic heterotopia and Hirsch- Mitnick pyloroplasty Well 8 and 18 yrs. p.o.
17 1915 M 30	Anterior lower side of duodenum 5.5 cm. from pylorus	Small without. Inflamma- tory changes	L.U.Q. pain yrs.	Possible duodenal ulcer	Excision of nodule. Severe recurrence of symptoms yr p.o.
18 1915 F 6	Common duct Yes	Nodule (size?). Marked inflammatory changes with lymphocytic infiltration and necrosis	Gas and indigestion 10-15 yrs.	Nonfunctioning gallblad- der with stones	Cholecystectomy; drainage of common duct (com- mon duct increased to twice normal size). Well 10 yrs. p.o.
19 1916 M 25	Outlet of common duct. Subserosa	mass in diameter Car- cinomatous duodenal ul- cer overlying nodule. Malignant change of ac- cessory pancreas (?)	R.U.Q. p. in 4 mos Marked jaundice 5 mos Loss 27 lbs.	Stomach negative	Gallbladder enlarged 3-4 times normal size. Com- mon duct dilated. Trans- duodenal excision of nodule and duodenal adenocarcinoma. ul- cer. Drainage of gall- bladder. Died third day p.o. Paternity denied, brochopneumonia
20 1916 M 34	Gallbladder cm. from cystic duct. Subserosa	1x0.6 cm. None	Nausea and regurgitation. Intermittent jaundice 2 yrs.	Stomach negative	Cholecystectomy. Still dis- tressed 5 yrs. p.o.
21 1917 F 30	Between posterior wall of stomach and gastroesoph- ageal junction	8x3x1 cm. Cystic change	In 1914 yrs. 3 severe epiplo- ic of upper abdominal pain with nausea and vomit- ing. Palpable epigastric mass. Loss 45 lbs. in 6 mos.	Stomach negative. Gall- bladder nonfunctioning with stones	Accessory pancreatic mass removed. Marginalization of pancreatic cyst. G. 11/12 3/4 d. al d. Well until yrs. p.o. Died from "heart tack"
22 1917 F 20	Transverse mesocolon No	Length—10 cm. Width— 4.5 cm. .5 cm. Thick- ness—1.5 cm. Hetero- topia pancreatic cyst containing plasma, largest 4 mm. in diameter	Recurrent epigastric pain with vomiting	Stomach negative	Removal of tumor. Patho- factory 8 yrs. p.o. After trouble with pancreatic diabetes
23 1918 M 23	Abdominal wall (in om- phaloenteric cyst, 5 cm. in diameter). Sub- serosa of small bowel epithelium Yes	Cyst cm. in diameter. Fat necrosis with acut- e foreign body giant cells in surrounding tis- sue	Intermittent nausea, in- dignity and drainage in umbilical region since childhood		Removal of cyst intact. Excellent health. No recurrence of symptoms yrs. 4 mos. p.o.
24 1920 M 27	Tip of Meckel's divertic- ulum. Subserosa Yes	cm. in diameter None	Periodic attacks of "bilious- ness" yrs.	Gallbladder normally func- tioning	Removal of diverticulum. Appendectomy Well 4 yrs. p.o.
25 1921 M 4 mos.	Tip of ileal diverticulum Subserosa No	1.5x0.5 cm. Necrosis and hemorrhage	Crying and vomiting 1914 at 2 1/2 h. 1/2 "sausage-like" mass pal- pated over right flank		Excision 5 cm. gas- trotomy bowel. Hirsch enterostomy. Died 5 hrs. p.o. Shock

Fourteen cases were unconfirmed cases of pancreatic heterotopia which we interpreted as clinically significant. The heterotopic pancreatic tissue diagnosed grossly as such by the surgeon in these cases, seemed to be the

cause of persistence or recurrence of symptoms after an operation performed on an organ bearing lesions which could not explain the symptoms present.

Twenty seven cases were unconfirmed cases

TABLE II—CASES OF PANCREATIC HETEROTOPIA RECORDED IN THE LITERATURE SINCE FAUST AND MUGGETT'S REVIEW IN 1939

*Cases not mentioned in Faust and Muggett's review but recorded in the literature prior to 1939.

†Ca = malignant lesion in heterotopic pancreatic tissue.

Int. = producing intussusception and causing hypopycemia.

Dev. = diverticulum of the duodenum.

P.V. = papilla of Vater obstructed by accessory pancreatic gland.

P.O. = pyloric obstruction.

of pancreatic heterotopia in which the heterotopic pancreatic tissue diagnosed grossly by the surgeon as such, was found incidentally during the course of an operation performed for some other surgical condition and was thought not to be of clinical significance.

GENERAL CONSIDERATIONS

Definition. Pancreatic heterotopia is defined as being the presence of pancreatic tissue outside its usual or habitual location and without anatomic relation either of continuity or of vascularization with the pancreas proper.

Literature. A complete review was made first of the early literature and second of the recent literature (Tables II and III). As precisely as we can determine, from 1727 to March, 1944, approximately 430 cases have been recorded in the literature to which we add the cases of our series (Table III) which includes 41 authentic cases and 41 unconfirmed cases.

Embryology and hypotheses of origin. Arcy gave a very clear description of the organogenesis of the pancreas. The classical descriptions are generally in agreement as far as the number and general topography of the pancreatic anlagen are concerned. They differ however when it comes to describing the phases through which the anlagen go in order to form the definitive pancreas. In 1939 Delmas presented his findings after following the evolution of the pancreas on reconstructions made by Born's method on human embryos from 5 to 27 millimeters in length. Delmas concluded that the total pancreas is completed at the 27 millimeter stage. According to his research, which was the most recent and thorough work that we found on this subject, the dorsal pancreas forms the head of the pancreas (primitive dorsal anlage) and the body and tail of the pancreas (bud from the dorsal anlage). The ventral pancreas forms the preduodenal process of the pancreas minor of Winslow and reinforces the dorsal part of the head of the pancreas. The ventral pancreas is the only anlage that tends to encircle the duodenum.

Practically all the concepts of the etiology of heterotopic pancreatic tissue maintain that

this anomaly is antenatal in origin. It is evident that one single concept does not explain all cases however much basis of truth it possesses. Our attitude in regard to these hypotheses is eclectic. Of those concepts presented three deserve mention for being ones that seem most logical to us and that are based on embryologic knowledge—namely, Horgan's, Lordy's and Warthin's concepts. Horgan expressed the belief that before the coalescence between the two anlagen takes place during the partial circumrotation of the posterior and anterior pancreatic anlagen, when there is a migration of the body upward

the branching ducts, as a result of the organs being packed together come into contact with the walls of the mesentery, stomach, or in the walls of the duodenum in the opposite direction. On testine growing in the opposite direction because these they become engrafted because of noninflammatory adhesions of fetal life. Later during the growth and movements of the gland the attached part is pulled off and may continue to live incorporated as a graft in the gastric duodenal or intestinal wall or mesentery. The germinative cells, from which all the histologic units of the pancreas can develop are present in these buds or attached portions derived from the primitive anlage

This graft may find suitable environment and continue to live and develop into a small separate piece of pancreatic tissue constituting a pancreatic heterotopia with all the functions of the normal pancreas.

Lordy explained the presence of an accessory pancreas by stating that it is due to persistence or incomplete regression of the left ventral anlage which is normally destined to atrophy. Warthin described his concept of the origin of pancreatic heterotopia as follows:

It is probable that accessory pancreatic tissue is formed from lateral budding of the rudimentary pancreatic ducts as they penetrate the intestinal wall, the mass of pancreatic tissue thus formed being snared off and carried by the longitudinal growth of the intestine either upward or downward.

Incidence The incidence of heterotopic pancreatic tissue not only at necropsy but at operation was studied from reports in the literature and from our own findings in the surgical records and those of the Section of Anatomic Pathology of the Mayo Clinic. It is that the incidence at necropsy varies

TABLE V — PRECISE HISTOLOGIC LOCATION OF THE HETEROTOPIC PANCREATIC TISSUE IN 26 CASES

Location	Symptoms	No symptoms	Total cases	Per cent
In submucosa only	0	2	24	92
In submucosa and infiltrating muscular fibers	1		6	23
Between muscle fibers only			4	15
On the submucosa or serosal surface only			2	8
In the submucosa between the muscle fibers and in the subserosal tissue			4	15
Total	18	2	20	100

from 0.6 per cent to 5.6 per cent of routine necropsies (Table IV). At operation heterotopic pancreatic tissue is found once in approximately every 500 operations in the upper abdominal region.

There is a higher incidence of surgical cases in the fourth, fifth, and sixth decades of life than in other decades but the anomaly has been found in patients of all ages both young and old including infants and newly born. In our series the youngest patient was 4 months and the oldest patient was 64 years of age.

Location We particularly endeavored to determine the usual and unusual locations of pancreatic heterotopias. The duodenum, stomach, and jejunum are the most common sites with an incidence for the three sites of almost 70 per cent: 27.7 per cent for the duodenum, 25.5 per cent for the stomach and 15.9 per cent for the jejunum (Table III). All the other unusual locations are mentioned in Table III.

Morphology Heterotopic pancreatic tissue usually presents itself as a single, firm and, when visible, yellowish (light yellow or cream color) or white, opaque, lobulated, round, or irregular node with granular surface. The maximal diameter of the node is usually 1 to 4 centimeters. Its appearance is like that of the pancreas itself or of a salivary gland. Larger masses may be found (Fig. 1).

The histologic picture of heterotopic pancreatic tissue is frequently the same as that of the pancreas itself, with acini forming lobules with ducts and islands of Langerhans (Fig.

TABLE VI.—SUMMARY OF 6 CASES* OF PANCREATIC HETEROTOPIA ASSOCIATED WITH HYPOGLYCEMIA AND HYPERINSULINISM, COLLECTED BY THE AUTHORS FROM REPORTS IN THE LITERATURE

Case number and author	Patient, sex and age, years	Symptoms	Operative findings	Pathologic findings	Results
Vercil 1914 (one case)		No clinical history. Hyperinsulinism?	Large tumor near tail of pancreas	Large islet cell tumor (neoplastic adenoma) arising in accessory pancreas	
1. Fanta 1937 (one case)	Male 37	*Hypoglycemia and hyperchloridria	Removal of walnut sized nodule of aberrant pancreas in duodenum	Heterotopic pancreatic tissue, not adenomatous	Partial relief from symptoms
2. Meyer Apr. 1937 (one case)	Female 34	*Hypoglycemia. Loss of weight. Abdominal tumor. Roentgenogram suggested tumor between stomach and colon-pancreatic cyst?	Cystic tumor in stomach wall with communication with pylorus with gastric ulcer. No communication with pancreas. Removal of tumor and pyloroplasty	Cystadenocarcinoma of aberrant intragastric pancreas (epitheliocyst masses with cells like Langerhans cells). Gastric ulceration	Recovery
4. White and Gildes Aug. 1937 (one case)	Female 33	*Hypoglycemia. Four episodes nocturnal confusion, restlessness, headache, dizziness and trembling. No result with medical treatment	Removal of calcified tumor outside pancreas. In connective tissue surrounding it. No connection with pancreas	Calcified adenoma 1.5 x 1.5 cm with islet cell masses. No mitotic figures	Complete relief. Gain in weight
5. Bellinger Aug. 194 (one case)	Male 53	*Very low hypoglycemia (proved specifically not to be hepatogenic). Fasting—mental confusion and faintness, convulsions and coma (worse with rosettes)	Tumor 10x10 cm found in retroperitoneal area between upper border head of pancreas and epigastric lobe of liver. Infestation of liver irreparable. Biopsy	Mitotizing islet cell carcinoma of aberrant pancreatic tissue in liver containing hypoglycemia-producing substances	Hypoglycemia relieved. Fasting ed. cessant. No large amount of glucose for relief
6. Radd and Walton Oct. 194 (one case)	Male 40	*Stupor—unconscious with low blood sugar level. Dramatic recovery with glucose (Parkinson's syndrome). Hypoglycemia	Nodule in gastrosplenic omentum 5 cm. from tip of tail of pancreas. Firm, round, 3 cm. in diameter. No connection with the main gland	Islet adenoma (pink on cut surface)	Physical and mental improves. Normal glucose tolerance test
7. Smith Feb. 194 (one case)	Female 43	*Weakness—later. Appetite for sweets. Hypoglycemia. Relief of symptoms with food	Excision of nodule from descending duodenum	Nodule 1.5 x 1.5 x 0.5 cm. Weight 1 g. with acini, ducts and diffuse islet cells (not adenomatous)	Weakness better. No h. g. Gained 10 lbs.
8. H. J. M. d. Stockton Aug. 1943 (one case)		Dizziness and weakness with inadequate feeding and strain. Intermittent episodes of acute mental upset, irresponsiveness and coma. Hypoglycemia	1st operation. Excision of islet nodule near end of tail of pancreas, together with a portion of pancreas. 2nd operation. Excision of round black nodule between pancreas and spleen	1st nodule: Islet cell adenoma, 7 cm. in diameter and smaller islet cells nodule 1 cm. in diameter	No relief from first operation. Patient well yr. after second operation
9. H. J. M. d. Stockton Aug. 1943 (one case)	Female 61	Nodule found incidentally	Nodule in proximal duodenum found incidentally during surgery following death from peritonitis	Schrenkian islet cell adenoma	Dead

*This table also includes Vercil's case, as well as one case of islet cell adenoma without hypoglycemia and one case of islet cell cystadenocarcinoma with hypoglycemia, from the literature.

a) There may however, be a lack of one or another histologic element of the normal pancreas.

In the majority of the cases reported as well as in our own cases the type of mucosa directly overlying the heterotopic tissue is the same as the type of mucosa normally corresponding to that particular portion of the gastrointestinal tract where the heterotopic pancreatic tissue is situated. We were not convinced of any direct relation continuity or transition between the glands and ducts of the mucosal epithelium and the acini and ducts of the heterotopic pancreatic

tissue. The only possibility of indirect connection would be by means of the excretory ducts of the heterotopic pancreatic tissue emptying into the lumen of the gastrointestinal tract through the ducts of the mucosal epithelium. The commonest histologic location of heterotopic pancreatic tissue was found to be the submucosa alone with an incidence of 53.8 per cent. The second most common type of involvement was infiltration between the longitudinal or circular muscular fibers or both, with an incidence of 23 per cent. The least common location was the serosal surface (Table V)

Cystic tumor in stomach wall with communication with pylorus with puritic ulcer. No communication with pancreas. Removal of tumor and pyloroplasty	Cystadenocarcinoma of aberrant intragastric pancreas (epitheliomatous masses with cells like Langerhans cells). Gastric ulceration	P
4. White and Gillies Aug., 1937 (one case)	Female 3	*Hypoglycemia. Fear episodes. Mental confusion, restlessness, headache, dizziness and trembling. No result with medical treatment	Removal of calcified tumor outside pancreas, in connective tissue surrounding it. No connection with pancreas	Calcified adenoma 11.5 cm with islet cell tissue. No mitotic figures	C
5. Bellenger Aug. 1941 (one case)	Male 33	*Very low hypoglycemia (proved specifically not to be hepatogenic). Fasting—mental confusion and lalanism, convulsions and coma (worse with metastases)	Tumor rosted cm. found in retroperitoneal area between upper border based of pancreas and apicalia lobe of liver. Induration of liver irre-movable. Biopsy	Metastasizing islet cell carcinoma of aberrant pancreatic tissue in liver containing hypoglycemia-producing substance	H p ti lar cor
6. Radd and Walton Oct., 1941 (one case)	Male 49	*Stupor—unconscious with low blood sugar level. Dramatic recovery with glucose (Parkinson's syndrome). Hypoglycemia	Nodule in gastroduodenal area 5 cm. from tip of tail of pancreas. Firm, rounded, 3 cm. in diameter. No connection with the main gland.	Islet adenoma (pink on cut surface)	Phys (a) si
7. Smith Feb. 1941 (one case)	Female 45	*Weakness—faint. Appetite for sweets. Hypoglycemia. Relief of symptoms with food	Excision of nodule from descending duodenum	Nodule 2x1x2x2 cm. Weight 1.5 gm. with acini, ducts and diffuse islet cells (not adenomatous)	N Gai
8. H Jan W d Stockton Aug. 1943 (one case)		Diabetes and weakness with inadequate feeding and thirst. Intermittent episodes of acute mental upset, irresponsiveness and coma. Hypoglycemia	At operation. Excision of black nodule near end of tail of pancreas, together with a portion of pancreas, and spleen. Excision of second black node between pancreas and spleen	At nodule: Islet cell adenoma, 7 cm in diameter and nodule: Islet cells; nodule cm in diameter	No fir Pat yr
9. H Jan W d Stockton Aug. 1943 (one case)	Female 6	Node found incidentally	Node in proximal duodenum found incidentally during necropsy following death from peritonitis	Sebaceous islet cell adenoma	Died

*This table also includes Vecchi's case, as well as one case of islet cell adenoma without hypoglycemia and one case of islet cell carcinoma with hypoglycemia, from the literature.

2) There may, however be a lack of one or another histologic element of the normal pancreas

In the majority of the cases reported as well as in our own cases the type of mucosa directly overlying the heterotopic tissue is the same as the type of mucosa normally corresponding to that particular portion of the gastrointestinal tract where the heterotopic pancreatic tissue is situated. We were not convinced of any direct relation continuity, or transition between the glands and ducts of the mucosal epithelium and the acini and ducts of the heterotopic pancreatic

tissue. The only possibility of indirect connection would be by means of the ex ducts of the heterotopic pancreatic emptying into the lumen of the intestinal tract through the ducts of the colal epithelium. The commonest location of heterotopic pancreatic tissue found to be the submucosa alone, incidence of 53.8 per cent. The second common type of involvement was between the longitudinal or circular fibers or both, with an incidence of 41 per cent. The least common location serosal surface (Table V)

TABLE VII.—PRODUCTION OF SYMPTOMS BY THE HETEROTOPIC PANCREATIC TISSUE, ACCORDING TO ITS LOCATION IN THE STOMACH, DUODENUM OR JEJUNUM IN 37 AUTHENTIC AND 37 UNCONFIRMED CASES FROM AUTHORS' SERIES OF PANCREATIC HETEROTOPIAS, IN WHICH THE FOREGOING LOCATIONS WERE FOUND

Location	With symptoms			Without symptoms			Total
	Authentic cases	Unconfirmed cases	Total	Authentic cases	Unconfirmed cases	Total	
Stomach*	9			4		4	13
Duodenum†	6		18	4	7		30
Jejunum‡				4	6		10
Total	15	14	29	12	13	25	64

*There was also one case of pancreatic tissue in gastric diverticulum (with symptoms).
 †There was also one case of pancreatic tissue in duodenum & jejunum (with symptoms).
 ‡There was also one case of pancreatic tissue in jejunal diverticulum (without symptoms).

Physiology. Special staining methods were utilized to determine whether or not heterotopic pancreatic tissue secretes enzymes. Mallory's (36,37) phosphotungstic acid hematoxylin stain was most satisfactory. Histologic evidence of acinar function in our cases was present in 76 per cent. In these cases, refractile zymogen granules could be seen in the apex or base of the acinar cells or scattered all over inside these cells (Fig. 3). An investigation was carried out in order to determine what influence this external secretion could have on the gastric acidity. As a result of the analysis of gastric contents in our cases, we cannot conclude that there is any significant deviation to indicate alkalization of the gastric acidity brought about definitely by functioning heterotopic pancreatic tissue in the stomach wall. We did not carry out a histologic study with any special staining

methods for types or functional activity of cells in the islands of Langerhans but we have no reason to disbelieve in the functional activity of the islets of normal appearance in heterotopic pancreatic tissue. We wonder whether heterotopic pancreatic tissue may not, to a certain extent, constitute a somewhat similar circumstance to a graft of a small fragment of pancreatic tissue.

It is of great practical importance, especially to the surgeon to note that hyperinsulinism and hypoglycemia have been observed associated with extrapancreatic, insulin-producing islet cell adenomas and adenocarcinomas (Table VI). If therefore exploration is being carried out in a case of hypoglycemia with definite "Whipple's essential triad" and after a thorough search, no tumor is found in the pancreas, the surgeon should look for heterotopic pancreatic

TABLE VIII.—FORTY THREE CASES OF PANCREATIC HETEROTOPIA COLLECTED FROM THE LITERATURE BY POPPI IN 1935 IN WHICH SYMPTOMS WERE PROVED AT OPERATION TO BE PRODUCED BY THE HETEROTOPIC PANCREATIC TISSUE

Clinical diagnosis and percentage	Location of heterotopic pancreatic tissue					Total
	Stomach	Duodenum	Jejunum	Gallbladder	Mechetti's diverticulum	
7 cases gastric or duodenal ulcer 30.23%	7					7*
10 cases gastropathy 23.26%	9					11†
7 cases cholelithiasis, hepatic colic or right upper quadrant syndrome 16.28%	3	3				7
9 cases pyloric stenosis 20.93%	9					9
Total	28	3				31

*Only the 30 cases in which no ulcer was found are included.

†In one case the location was both gastric and duodenal. These two notes account for the total number of 31 instead of 43 mentioned in the title of the table.

Fig. 1. Case 22, Table I. Mass of heterotopic pancreatic tissue removed from the mesentery of the transverse colon. Its dimensions were as follows: length 10 centimeters; width largest (globular end) 4.5 centimeters, smallest (neck) 3 centimeters; thickness, 3 centimeters. A cyst was found at the globular end of the elongated mass of heterotopic pancreatic tissue. The cyst contained stones (largest 4 mm.) and sandy material. Grossly at operation the mass gave the impression of a lymphosarcoma or of tuberculosis of lymph nodes.

tissue in its most common locations and also in such of the unusual sites as permit exploration.

Pathology. Pathologic changes have been found in heterotopic pancreatic tissue itself in the surrounding tissues or in both. Heterotopic pancreatic tissue presents the same pathologic changes as the pancreas, namely cysts, pancreatitis, hemorrhage, necrosis, and neoplastic change (benign and malignant). Data on 3 cases of cyst formation in heterotopic pancreatic tissue are presented in Table I (Fig. 4). An investigation was carried out to determine the presence of dilatation of the ducts in pancreatic dystopias. The ducts were

Fig. 2. Case 1, Table I. Portion of a mass of heterotopic pancreatic tissue measuring 3.5 by 3 by 1.5 centimeters on the posterior wall and lesser curvature of the stomach, showing acini and islands of Langerhans. Hematoxylin and eosin. $\times 88$.

found to be dilated in a large number of cases. Both benign and malignant changes in heterotopic pancreatic tissue have been observed. We feel that malignant change is more likely to take place in heterotopic pancreatic tissue than in the normally placed pancreas. The heterotopic pancreatic tissue is not always completely formed and differentiated. Both benign and malignant change would possibly be more likely to take place in an incompletely developed and less differentiated tissue in an aberrant location where it is subject to irritation than in a normal tissue in its usual site. There have been cases in the literature in which the malignant change had its origin traced back to heterotopic pancreatic tissue. It seems that there is little basis to believe in any connection between heterotopic pancreatic tissue and the histogenesis of carcinoids.

Pathologic changes sometimes occur in the tissues adjacent to the heterotopic pancreatic tissue, namely fat necrosis, inflammation, hemorrhage, ulceration, and diverticulum formation. All the foregoing pathologic changes were studied fully, especially ulceration of the mucosa overlying the dystopic pancreatic tissue, which may be the cause of gastroduodenal ulcers in a small number of cases. In such cases conservative surgical treatment

Fig. 3. Case Table I. Portion of a mass of heterotopic pancreatic tissue in the stomach wall. Staining method Mallory's phosphotungstic acid hematoxylin stain, with oil immersion lens. $\times 53$. The individual zymogen granules can be seen agglomerated at the apex of the acinar cells.

Fig. 4. Case 6, Table I. View from the serosal side of portion of gastric wall, measuring 7.5 centimeters in diameter (centered 1th cauterly) containing an intramural mass of heterotopic pancreatic tissue, measuring 3 by centimeters. Cysts can be seen grossly in the pancreatic tissue.

is indicated namely simple local excision of the ulcer together with the underlying misplaced pancreatic tissue mass. Data on 3 cases are presented in Table I. Formation of a diverticulum brought about by heterotopic pancreatic tissue was studied; data on 3 cases in which symptoms were caused by these lesions will be found in Table I.

Clinical significance. In 25 (61 per cent) of the 41 authentic cases of pancreatic heterotopia the heterotopic pancreatic tissue was proved at operation to have been the only

Fig. 5. Case Table I. Mass of heterotopic pancreatic tissue measuring 3.5 by 3 by .5 centimeters on the lesser curvature and posterior wall of the stomach giving a roentgenologic image of an ovoid mass in midportion of stomach; its malignant nature could not be excluded roentgenologically.

lesion, the principal lesion or at least one of the lesions causative of symptoms for which the patient was submitted to surgical intervention. Of the 25 authentic cases in which there were symptoms, it was seen that in 9 (36 per cent) the heterotopic pancreatic tissue was located in the gastric wall. The incidence in this location in all authentic cases, with or without symptoms was 31.7 per cent. In 6 (24 per cent) of the cases in which there were symptoms the location was in the duodenal wall. The incidence in this location in all authentic cases was 24.4 per cent. There were no cases with jejunal location presenting symptoms but the incidence in this location in the authentic cases without symptoms was approximately 10 per cent (Tables VII and VIII). For the cases in which heterotopic pancreatic tissue occurred in other locations see Table III. In most of the cases of pancreatic heterotopia in which there were symptoms, the location was either gastric or duodenal. Proportionately the cases of heterotopia with gastric location contribute more than the ones with duodenal location to the number of cases with symptoms. In 13 cases reviewed there was persistence of symptoms possibly because of failure to remove a supposed pancreatic heterotopia at operation.

Symptomatology. There is no single symptom complex for pancreatic heterotopia. The symptoms, of course vary according to the

Fig. 6. Case 1 Table I Mass of heterotopic pancreatic tissue measuring 3.5 by 3 by 1.5 centimeters on the lesser curvature and posterior wall of the stomach. The patient gave a history simulating that of duodenal ulcer and a loss of weight. The tumor was mistaken clinically roentgenologically and at operation for an adenocarcinoma of the stomach. The tumor had been sectioned for examination when this picture was taken.

Fig. 7. Case 1 Table I Heterotopic pancreatic tissue mass, showing pancreatic tissue extending between the muscular bundles. Grossly the tumor seemed to infiltrate the muscular coat of the stomach. Hematoxylin and eosin. $\times 70$.

which were caused by the heterotopic pancreatic tissue as proved by the relief of symptoms after its removal in practically all the cases. Data on 3 cases are presented in Table I (Fig. 10).

Among our 10 cases of pancreatic heterotopia with a gastric location there was 1 case in which pyloric obstruction was observed

different locations in which heterotopic pancreatic tissue may be found. The symptoms produced however are generally similar to those produced by gastroduodenal lesions namely symptoms of gastric ulcer duodenal ulcer pyloric obstruction cholecystitis obstruction of the common duct, chronic or acute appendicitis or indeterminate digestive symptoms. The group of authentic cases in which there were symptoms was reviewed in subgroups divided according to location and the complication or disturbance that the anomaly caused. There were 10 authentic cases of pancreatic heterotopia with a gastric location and presenting symptoms which were caused by the heterotopic pancreatic tissue as proved by the relief of the symptoms after its removal. Data on 6 cases are presented in Table I (Figs. 5, 6, 7, 8 and 9). There were 7 authentic cases of pancreatic heterotopia with duodenal location and presenting symptoms

Fig. 8. Case 2 Table I Gastric nodule of heterotopic pancreatic tissue 1.5 centimeters in diameter producing a filling defect near the greater curvature just proximal to the pylorus. It appeared like a leiomyoma grossly at operation.

Fig. 9. Case 7. Table I. Nodule of heterotopic pancreatic tissue measuring 8 millimeters in diameter in the submucosa of the posterior wall of the prepyloric region of the stomach. The overlying gastric mucosa is pitted.

Fig. 10. Case 5. Table I. Nodule of heterotopic pancreatic tissue measuring 1.5 by 0.8 centimeter in the anterior wall of duodenum immediately below pylorus. The mass looked like fibroma grossly before operation.

Data on this case are presented in Table I (Figs. 11 and 12). Seventeen cases of pyloric stenosis which were secondary to the presence of heterotopic pancreatic tissue were collected by Krieg from the medical literature in 1939 and published in 1941. We found in the literature 5 additional cases of heterotopic pancreatic tissue causing pyloric obstruction from the time of Krieg's review in 1939 up until March, 1944. Krieg mentioned a group of 23 cases of Poppl's series which he interpreted as having been produced by local spasm of the intestinal wall. In his opinion the difference between the cases of stenosis and those of spasm is that of time and the degree of irritation.

Hypertrophy of the muscular coat was evidenced grossly and microscopically in 11 out of 19 authentic cases of our series of pancreatic heterotopia in the gastrointestinal tract. In our series of authentic cases, there were 2 cases of Meckel's diverticulum containing heterotopic pancreatic tissue. Data on

a case of ileal intussusception brought about by an ileal diverticulum containing pancreatic tissue will be found in Table I. Data on a case of pancreatic heterotopia in the wall of the gallbladder are presented. This case is of interest in the light of Colp and Doubilet's studies on the clinical significance of pancreatic reflux. Data on a case of obstruction of the common duct caused by heterotopic pancreatic tissue are presented in Table I. The possibility of duodenal adenocarcinoma arising in dystopic pancreatic tissue in the ampulla of Vater and in the papilla of Santorini is suggested. A study of the pathogenesis of the disturbances and symptoms caused by heterotopic pancreatic tissue was made. The pathologic changes have an influence on the production of symptoms.

Diagnosis. The clinical, the roentgenologic, the operative and the pathologic diagnosis of pancreatic heterotopia were reviewed. Of the cases in which the heterotopic tissue was in a gastric location the diagnosis of a benign

Fig 11. Case 8, Table I. Annular mass of heterotopic pancreatic tissue on the serosal surface of the pyloric ring. The roentgenologic report was as follows: "Annular lesion involving pylorus, prepyloric area and base of duodenum; shallow ulceration impossible to exclude malignancy."

tumor was made in 50 per cent of ulcer in 20 per cent, and of malignant tumor in 20 per cent. The mass was missed in 10 per cent. In only 1 of the cases in which the location was duodenal was the diagnosis of duodenal tumor made. In all the others the roentgenologic diagnosis of duodenal ulcer was made although in only 1 was an ulcer actually present. The preciseness of the roentgenologist's diagnosis of gastric polyps may be seen from his reports in 6 of our cases in which the masses were of relatively minute proportions. The diagnosis of a gastric or duodenal polyp is the nearest that one can actually get to the precise and final diagnosis made by the pathologist, although in 3 cases of our series the exact nature of the mass was suspected. Apparently analysis of gastric contents is of no avail in determining possible alkalinity or reduced acidity of gastric contents due to alkalization of the gastric juice from pancreatic secretion flowing from heterotopic pancreatic tissue although this possibility should be kept in mind. Gastroscopy might

Fig 12. Case 8, Table I. Specimen 12 centimeters of stomach and 1.5 centimeters of duodenum. Heterotopic pancreatic tissue forming an annular mass, 3 centimeters in diameter on the serosal surface of the pyloric ring. The tumor in the picture is included between the points of the two arrows. It was causing pyloric obstruction and loss of weight clinically, roentgenologically and grossly at operation it was mistaken for an adenocarcinoma of the stomach.

possibly be an aid in the diagnosis by confirming the roentgenologic finding or by revealing the tumor to be intramural, covered by normal mucosa and not ulcerated as in gastric carcinoma. When visible on the serosal surface a pancreatic heterotopia is grossly recognizable but there should always be a confirmative diagnosis by the pathologist. In 18 surgical cases of pancreatic heterotopia in which a notation was made of the surgeon's impression from gross examination we reviewed the operative diagnosis made prior to the pathologist's report. In approximately 29 per cent the pancreatic heterotopia gave the impression of a malignant lesion. In 50 per cent the diagnosis of a benign lesion was made. In a little more than 22 per cent the nature of the mass was recognized correctly as being

TABLE IX.—SURGICAL PROCEDURES PERFORMED IN 25 CASES OF PANCREATIC HETEROTOPIA

Surgical procedure	Cases
Biopsy	1
Partial gastrectomy	0
Removal of tumor	10*
Resection of gangrenous bowel (Intussusception)	1
Cholecystectomy	2†
Diverticulectomy and appendectomy	
Total	5

*Resection of an associated pancreatic cyst, as performed in case cholecystectomy and exploration of the lumen of gallbladder case and in case transduodenal removal of duodenal adenocarcinoma and cholecystectomy.

†Exploration of the common duct was performed in case.

heterotopic pancreatic tissue. The pathologist's diagnosis based on examination of frozen sections at the time of operation is essential. The correct diagnosis was promptly made in practically all the cases.

Surgical treatment. There are two circumstances in which a pancreatic heterotopia may be found at exploration: it is either causative of symptoms or it is only an incidental finding. In Table IX we listed the operative procedures performed in 25 cases of our series of pancreatic heterotopia that were clinically significant. In no case was persistence or recurrence of symptoms observed following the complete radical or conservative removal of the pancreatic heterotopia when this lesion was the only cause of the complication and referred symptoms. In some of the cases of our series a more conservative operative procedure rather than gastrectomy could have been performed probably with equally good final results had it been possible for the surgeon to know that he was dealing with a benign lesion. In only 1 case in our series did a patient die from a complication associated with a pancreatic heterotopia, namely ileal intussusception.

When the pancreatic heterotopia is located in the stomach or duodenum simple local excision when feasible is sufficient to bring about relief of symptoms. At times careful duodenal reconstruction or pyloroplasty may have to be carried out. Since as is shown by the abstracts of the case records, in most instances a roentgenologic diagnosis of ulcer, tumor, carcinoma, or polyp was made preoperatively it is understandable why in 10 instances partial gastrectomy was chosen by the surgeon as the procedure to be performed.

It would be difficult to tell by palpation the nature of the lesion and biopsy of gastric lesions is at best frequently indeterminate. Therefore by and large with carcinoma so common in the stomach and pancreatic heterotopia so uncommon it would be to the patient's best interest to elect gastric resection. Frequently one of the modifications of the Billroth I operation would be possible and indicated when the lesion is found in the lower third of the stomach. In higher lesions a Polya operation or one of its modifications would be suitable.

In the presence of a diverticulum associated with heterotopic pancreatic tissue removal of the diverticulum together with the heterotopic tissue is indicated with simple local excision alone or possibly with pyloroplasty or duodenal reconstruction. In the presence of muscular hypertrophy possibly associated with pyloric stenosis, excision and pyloroplasty are indicated.

Whenever pathologic changes are encountered in other organs with the presence of a pancreatic heterotopia and the former seem to have more to do with the patient's symptoms than the latter the surgeon should not underestimate the potentiality for production of symptoms or actual present clinical significance of the pancreatic heterotopia, complete removal of which should be carried out. The operative procedure advised for pancreatic heterotopia in locations other than the stomach and duodenum is complete but simple extirpation but no generalizations can be made so varied are the locations. One has to depend on one's surgical judgment in the particular case. As far as the pancreatic heterotopia is concerned one can be as conservative as possible. In several of our surgical cases of clinically significant pancreatic heterotopia operation had been performed for some other condition prior to admission of the patient to the Mayo Clinic and at a time when the heterotopic pancreatic tissue was not clinically significant. If the heterotopic tissue had been removed at this time the later operation for its removal could have been avoided. Whenever heterotopic pancreatic tissue is found in the stomach or duodenum incidentally during the course of an operation

for some other surgical lesion its excision is indicated to avoid future trouble unless the risk of the procedure outweighs the advantages of removal. A jejunal pancreatic heterotopia found incidentally during the course of an operation for some other condition may be left undisturbed with a fair chance that no complications will be observed subsequently unless such pathologic changes are present that there is a question as to either its present or its future clinical significance. The same general rule as the aforementioned one would hold true for pancreatic heterotopia in other locations although surgical judgment for the particular location varies.

SUMMARY AND CONCLUSIONS

There are approximately 470 recorded cases of pancreatic heterotopia. Pancreatic heterotopia is observed fairly frequently at routine necropsies. We found an incidence of 1 case of pancreatic heterotopia in approximately every 500 operations in the upper abdominal region. The incidence of pancreatic heterotopia is highest in the fourth, fifth and sixth decades of life.

The ratio of males to females is almost 3 to 1. The most common location is in the stomach, duodenum and jejunum where the incidence is almost 70 per cent. In the majority of the cases the mass of heterotopic pancreatic tissue is single and its diameter usually varies from 1 to 4 centimeters.

The histologic picture of heterotopic pancreatic tissue is frequently the same as that of the pancreas itself. The commonest histologic location of heterotopic pancreatic tissue in our series was the submucosa alone. There frequently is intermuscular infiltration. In the vast majority of the cases there is histologic evidence of acinar function. There is no apparent change in the results of analysis of gastric contents associated with a pancreatic heterotopia.

Hypoglycemia and hyperinsulinism have been observed in association with heterotopic pancreatic tissue presenting both benign and malignant change in its insular portion. If exploration is being carried out in a case of hypoglycemia with definite Whipple's essential triad and after a thorough search no

tumor is found in the pancreas the surgeon should search for heterotopic pancreatic tissue in its most common locations and also in the unusual sites that are capable of exploration. Both adenomas and adenocarcinomas of islet cell type may be present without clinical evidence of hypoglycemia.

Heterotopic pancreatic tissue presents the same pathologic changes as the pancreas itself. In many cases the ducts are found dilated. Malignant change is more likely to take place in heterotopic pancreatic tissue than in the pancreas proper. Pancreatic heterotopia may be the cause of several types of pathologic changes in the adjacent tissues, namely fat necrosis, inflammation, ulceration, hemorrhage, necrosis and formation of a diverticulum.

In a high percentage of surgical cases of pancreatic heterotopia (61 per cent of our cases) the heterotopia is found to be of clinical significance. The location is usually gastric or duodenal. Some of the rare adenocarcinomas of the duodenum may have had their origin in heterotopic pancreatic tissue either in the ampulla of Vater or in the papilla of Santorini. The syndromes presented by a pancreatic heterotopia are generally those of gastric or duodenal ulceration, cholecystic disease or indeterminate digestive symptoms.

The pathologic diagnosis with frozen section technique at the time of operation is of inestimable value. A mass of heterotopic pancreatic tissue can be mistaken for a malignant growth both roentgenologically and at operation with a consequent unnecessary operation. When the pancreatic heterotopia is clinically significant its simple excision when feasible is entirely sufficient for complete relief of symptoms. When found incidentally at operation its removal is indicated in the majority of cases.

SECONDARY SUTURE OF WAR WOUNDS

A Study of Methods and Results in an Overseas General Hospital

KNOWLES B LAWRENCE, M.D., F.A.C.S., and SOMERS H STURGIS M.D. F.A.C.S.
Boston Massachusetts

THE success of the U S Army Medical Corps policy of early débridement of wounds without primary suture in preventing serious infection was demonstrated repeatedly during World War II. It was equally well known that secondary healing of such débrided wounds by granulation and epithelization often consumed several months. Painful and disabling cicatrices, osteomyelitis, stiff joints and muscle atrophy were frequent complications of wounds allowed to heal by second intention. Psychoneurosis developed or aggravated during long hospitalization rendered many soldiers unfit for further combat duty. For the first 2 years after Pearl Harbor the tremendous wastes in man power and in hospital care resulting from such a slow healing were serious hindrances to the war effort.

The obvious answer to these problems was to effect closure of débrided wounds as early as consistent with safety. In World War I primary suture was practiced sometimes on selected wounds not more than 12 hours old (5). The percentage of successful healing in several series of primarily sutured wounds including a few joint wounds was excellent (from 66 to 94 per cent) but there was also a significant mortality rate. It was concluded as a result of those experiences that the use of the primary suture after débridement should be restricted to quiet periods in the fighting when the wounded patient could be kept in one hospital until healing was assured. The decision to close the rest depended largely on the reports from routine culture and smear taken at the daily dressing. Delayed primary suturing of wounds free from hemolytic streptococci, within the first 5 days was distinguished from the 'secondary suture' of all later closures in which inversion of skin edges and a granula-

ting base had developed. In both delayed primary and secondary closures a miscellaneous assortment of antiseptics had been previously applied to combat the nearly omnipresent infection. Reported results in small series of cases varied from 66 to 88 per cent of 'success' (1-5). In general the methods of early closure of wounds during World War I seemed either too narrow in selection of cases or too cumbersome in practice to be applicable to large numbers of wounds encountered under average conditions of combat.

Experiences reported from the Republican army in the Spanish Civil War obscured the issue in a sense for, there emphasis was placed on the plaster encasement treatment of serious extremity wounds (7). The primary missions of reducing fatality rates and obtaining reasonable healing of fractures despite unfavorable tactical situations were accomplished by this treatment. That better and more rapid healing might be obtained by early closures of such wounds in communication zone hospitals and with the help of modern chemotherapeutic agents was not envisaged at that time.

The use of chemotherapy in conjunction with radical débridement in World War II seemed to change the pathology of war wounds. The majority remained grossly as clean as any other surgical wounds, if infection was not introduced by changing the dressing at least for a week or 10 days following débridement. In overseas base hospitals surgeons guided by this finding tried secondarily suturing these wounds during this initial period when they were 'clean'. By 1944 this procedure was being performed routinely during the first 10 days after débridement in many U S Army hospitals of the Mediterranean Theater.¹ Results were gratifyingly good. In June 1944 Kirtley and Trabue reported 92.7 per cent

¹Formerly members of the Surgical Service, 6th General Hospital, U S Army.

²See Circular letter No. 16, The Surgeon, North African Theater of Operations, United States Army April 19 1944.

successful healing in one group of 217 'delayed primary' sutures, and only 3 infected wounds in another group of 30 cases studied in detail. In the latter group 71 individual wounds were sutured 4 to 5 days after wounding. Wilson obtained healing without infection in 85 per cent of 224 wounds secondarily sutured when less than 10 days old. In wounds sutured after 10 days the primary healing rate was reduced to 38 per cent. Wilson's study was based on 305 total wounds in 209 patients. The results in both series are colored somewhat by the fact that compound fracture cases apparently were not included.

The work of British surgeons on this important subject as reported to the Congress of Central Mediterranean Force Army Surgeons, Rome Italy February 1945 is of special interest. After a somewhat longer period of participation in the war the British were fully aware of the advantages of early closure of wounds. Their efforts as described at that meeting were being directed toward the improvement of results in such wound handling chiefly by the local use of chemotherapeutic agents. Murray reported that 91 per cent of 500 fresh wounds treated locally with a penicillin powder at time of suture healed successfully after delayed primary suture¹ in contrast to 75 per cent successful healing in 229 proflavine treated wounds. In a paper entitled 'Early Closure of Compound Fractures' at the same congress Hendry reported 60 per cent of his cases with complete healing of the skin over major fractures of long bones within 6 weeks after delayed primary suture.

Secondary closure was performed on the wounds of approximately 2200 patients at the 6th General Hospital situated near Rome, Italy during July, August, and September of 1944. The present report is based chiefly on a series of 1110 of these patients with more than 2700 individual wounds. Most of the balance consisted of a number of patients operated upon during this period which could not be included solely because the press of work at times made it impossible to obtain and record the necessary data. At least 100 patients were evacuated to the rear to create bed space before healing results could be evaluated. (ulte

¹Synonymous with our term "secondary suture."

a few cases, in which wounds were limited to amputations or to wounds of the fingers, toes or face were excluded also because they represented a different sort of surgical problem. Aside from these specific omissions the series was unselected and included various types of soft tissue wounds as well as those associated with compound fractures. Thirty different surgeons operating on these patients used their own judgment in carrying out the details of the general policy.

GENERAL POLICY

A great influx of recent casualties arriving from forward hospitals with wounds already debrided made necessary the adoption of mass production methods of surgical management. This consisted principally of a systematic performance of secondary suturing in the early clean period within a week or 10 days after débridement.

Guided by our own previous experience and reports from other hospitals, it was the policy to leave the dressings unchanged until the patient's arrival in the operating room. However a few wounds required preoperative inspection because of unexplained fever, pain, excessive drainage or hemorrhage. In general this method represented a vast saving in time, materials and discomfort to the patient over the daily dressing regimen of World War I. Many patients received sulfadiazine by mouth, and this was often continued for several days after operation. The use of penicillin parenterally was not routine and was usually restricted to severe compound fracture wounds into joints, and grossly infected wounds. Transfusions of blood and plasma, vitamins and other supportive treatment were used as indicated. Most surgeons preferred a time interval of at least 48 hours between admission and secondary suture to allow for rest and observation.

In the group of cases here studied 96 per cent were admitted to this hospital in time to be scheduled for secondary closure before the tenth day following their débridement. Occasionally secondary closure was contraindicated by the condition of the patient or his wound. It was soon noted that the clinical appearance of the wound on the fifth or sixth day after

débridement suggested that this was the most favorable time for suturing.

On first inspection of these wounds in the operating room we were surprised at the small percentage which seemed unsuitable for closure because of gross signs of necrosis. In a series of over 300 wounds personally observed by the authors, this was less than 5 per cent, and testified to the excellent results from débridement and chemotherapy usually penicillin at forward hospitals. Culturing of wounds for determination of bacterial flora was impractical as a routine procedure.¹ Wounds containing thin purulent exudate, with, at times slight reddening of skin at margins and turgidity of tissues proved to be trouble makers. Such wounds were very apt to become septic and break down if sutured in that condition and did much better after preliminary treatment for 24 hours or more with wet dressings of which the most effective seemed to be penicillin solution (500 or 1000 units to 1 c.c.) Patches of fibrin adherent to otherwise fairly dry and innocent looking wounds usually did not deter healing. A number of wounds, though clean were of such a large size or so located that they could not be closed completely by secondary suturing. In some the unsutured part was left to heal spontaneously. In others this area was covered with a split thickness skin graft immediately or at a later date. The longest wound measured 70 centimeters extending from the lateral aspect of the hip to the knee. It healed satisfactorily after secondary suturing. The greatest number of wounds in one patient was one hundred.

TECHNICAL ASPECTS OF SECONDARY SUTURING

Anesthesia Intravenous sodium pentothal was the most commonly used anesthetic agent. There were no deaths attributable to pentothal in this series. Novocain locally was used in about one quarter of the cases. Infiltration of subcutaneous tissue from the wound surface seemed simpler and caused less discomfort to the patient than block anesthesia through the intact skin.

¹The wisdom of this decision to omit routine wound cultures was confirmed later by the work of Beatty and Thomson who found that only 20 per cent of series of 64 grossly clean wounds contained pathogenic bacteria and that satisfactory healing was obtained after secondary suturing in 6 per cent of even these "infected" wounds.

Surgical technique Accurate approximation of the entire depth of the wound without excessive tension was the primary objective of the operation. It was felt that the less cutting or surgical manipulation of any kind the less risk there would be of breaking through the natural defenses against infection that had been mobilized about the wound edges in the preceding days. Wounds more than a week old, however generally require freshening or freeing up of the margins to obtain apposition of the skin edges without inversion. Wounds over large muscle bellies, as in the thigh, but tocks, or arm, often presented a problem in closure unique to war injuries. The swelling of injured muscles at times produces wide retraction of wound margins. Where there is no significant skin loss the degree of tension required to close these wounds accurately reflects the amount of edema to be reduced. Therefore, marked tension in the closure of these particular wounds is not only tolerated but proportionately necessary to relieve lymphostasis and congestion and undermining the edges to avoid this tension in such wounds is undesirable. Where there was major skin loss extensive undercutting was resorted to without hesitation in order to close the wound. Advancement and rotation of contiguous skin flaps occasionally permitted closure of wounds in which even wide undermining did not accomplish this result. Due to experience with flexion deformities and recurrent breakdown of scars which were situated vertically over joints, particularly in the popliteal space we utilized these maneuvers to obtain more nearly transversely placed suture lines in such areas. Black silk was the most commonly used suture material, employed sometimes in conjunction with silkworm gut. The latter seemed to cause less tissue reaction and cutting through when under tension. The deep fascia was approximated as a separate layer in a few cases. Several instances of postoperative wound infection were seen with extrusion of nonabsorbable sutures however, and therefore buried sutures were avoided as a general policy. If the edges of aponeurosis or fascia are included in the deep bites of vertical mattress sutures, solid healing will be obtained in most cases. Of the few postoperative mus-

successful healing in one group of 217 delayed primary sutures, and only 3 infected wounds in another group of 30 cases studied in detail. In the latter group 71 individual wounds were sutured 4 to 5 days after wounding. Wilson obtained healing without infection in 85 per cent of 224 wounds secondarily sutured when less than 10 days old. In wounds sutured after 10 days the primary healing rate was reduced to 38 per cent. Wilson's study was based on 305 total wounds in 209 patients. The results in both series are colored somewhat by the fact that compound fracture cases apparently were not included.

The work of British surgeons on this important subject as reported to the Congress of Central Mediterranean Force Army Surgeons, Rome, Italy, February 1945 is of special interest. After a somewhat longer period of participation in the war the British were fully aware of the advantages of early closure of wounds. Their efforts as described at that meeting were being directed toward the improvement of results in such wound handling chiefly by the local use of chemotherapeutic agents. Murray reported that 91 per cent of 500 flesh wounds treated locally with a penicillin powder at time of suture healed successfully after delayed primary suture¹ in contrast to 75 per cent successful healing in 229 proflavine treated wounds. In a paper entitled "Early Closure of Compound Fractures" at the same congress Hendry reported 60 per cent of his cases with complete healing of the skin over major fractures of long bones within 6 weeks after delayed primary suture.

Secondary closure was performed on the wounds of approximately 2200 patients at the 6th General Hospital situated near Rome, Italy during July, August, and September of 1944. The present report is based chiefly on a series of 1110 of these patients with more than 2700 individual wounds. Most of the balance consisted of a number of patients operated upon during this period which could not be included solely because the press of work at times made it impossible to obtain and record the necessary data. At least 100 patients were evacuated to the rear to create bed space before healing results could be evaluated. Quite

a few cases, in which wounds were limited to amputations or to wounds of the fingers, toes, or face, were excluded also because they represented a different sort of surgical problem. Aside from these specific omissions the series was unselected and included various types of soft tissue wounds as well as those associated with compound fractures. Thirty different surgeons, operating on these patients, used their own judgment in carrying out the details of the general policy.

GENERAL POLICY

A great influx of recent casualties arriving from forward hospitals with wounds already debrided made necessary the adoption of mass production methods of surgical management. This consisted principally of a systematic performance of secondary suturing in the early clean period within a week or 10 days after debridement.

Guided by our own previous experience and reports from other hospitals it was the policy to leave the dressings unchanged until the patient's arrival in the operating room. However a few wounds required preoperative inspection because of unexplained fever, pain, excessive drainage or hemorrhage. In general this method represented a vast saving in time, materials and discomfort to the patient over the daily dressing regimen of World War I. Many patients received sulfadiazine by mouth, and this was often continued for several days after operation. The use of penicillin parenterally was not routine and was usually restricted to severe compound fractures, wounds into joints, and grossly infected wounds. Transfusions of blood and plasma, vitamins and other supportive treatment were used as indicated. Most surgeons preferred a time interval of at least 48 hours between admission and secondary suture to allow for rest and observation.

In the group of cases here studied 96 per cent were admitted to this hospital in time to be scheduled for secondary closure before the tenth day following their debridement. Occasionally secondary closure was contraindicated by the condition of the patient or his wound. It was soon noted that the clinical appearance of the wound on the fifth or sixth day after

¹Synonymous with our term "secondary suture."

débridement suggested that this was the most favorable time for suturing.

On first inspection of these wounds in the operating room we were surprised at the small percentage which seemed unsuitable for closure because of gross signs of necrosis. In a series of over 300 wounds personally observed by the authors this was less than 5 per cent and testified to the excellent results from débridement and chemotherapy usually performed in forward hospitals. Culturing of wounds for determination of bacterial flora was impractical as a routine procedure.¹ Wounds containing thin purulent exudate with, at times slight reddening of skin at margins and turgidity of tissues proved to be trouble makers. Such wounds were very apt to become septic and break down if sutured in that condition and did much better after preliminary treatment for 24 hours or more with wet dressings of which the most effective seemed to be penicillin solution (500 or 1000 units to 1 c.c.). Patches of fibrin adherent to otherwise fairly dry and innocent looking wounds usually did not deter healing of such a large size or so located that they could not be closed completely by secondary suturing. In some the unsutured part was left to heal spontaneously. In others this area was covered with a split thickness skin graft immediately or at a later date. The longest wound measured 70 centimeters extending from the lateral aspect of the hip to the knee. It healed satisfactorily after secondary suturing. The greatest number of wounds in one patient was one hundred.

TECHNICAL ASPECTS OF SECONDARY SUTURING

Anesthesia. Intravenous sodium pentothal was the most commonly used anesthetic agent. There were no deaths attributable to pentothal in this series. Novocain locally was used in about one quarter of the cases. Infiltration of subcutaneous tissue from the wound surface seemed simpler and caused less discomfort to the patient than block anesthesia through the intact skin.

¹The authors of this document do not provide wound cultures was confirmed later by the work of Berth and Thomson who found that only 30 per cent of a series of 6 severely torn wounds contained pathogenic bacteria. 1 that satisfactory healing was obtained. 27 secondary suturing in 8 per cent of even these in closed wounds.

Surgical technique. Accurate approximation of the entire depth of the wound without excessive tension was the primary objective of the operation. It was felt that the less cutting or surgical manipulation of any kind the less risk there would be of breaking through the natural defenses against infection that had been mobilized about the wound edges in the preceding days. Wounds more than a week old however, generally require freshening or freeing up of the margins to obtain apposition of the skin edges without inversion. Wounds over large muscle bellies as in the thigh but of the arm, often presented a problem in closure unique to war injuries. The swelling of injured muscles at times produces wide retraction of wound margins. Where there is no significant skin loss the degree of tension required to close these wounds accurately reflects the amount of edema to be reduced. Therefore marked tension in the closure of these particular wounds is not only tolerated but proportionately necessary to relieve lymphostasis and congestion and undermining the edges to avoid this tension in such wounds is undesirable. Where there was major skin loss extensive undercutting was resorted to without hesitation in order to close the wound. Advancement and rotation of contiguous skin flaps occasionally permitted closure of wounds in which even wide undermining did not accomplish this result. Due to experience with flexion deformities and recurrent breakdown of scars which were situated vertically over joints particularly in the popliteal space we utilized these maneuvers to obtain more nearly transversely placed suture lines in such areas. Black silk was the most commonly used suture material employed some times in conjunction with silk worm gut. The latter seemed to cause less tissue reaction and cutting through when under tension. The deep fascia was approximated as a separate layer in a few cases. Several instances of post-operative wound infection were seen with extrusion of nonabsorbable sutures however, and therefore buried sutures were avoided as a general policy. If the edges of aponeurosis or fascia are included in the deep bites of vertical mattress sutures solid healing will be obtained in most cases. Of the few postoperative mus-

cle hernias observed only an occasional one has been symptomatic.

At first many deep wounds were drained at the time of secondary suture because of potential dead space retained blood clot or border line infection. With more experience this was found rarely necessary except in cases of compound fractures of the larger bones. Dependent stab wound drainage employing soft Penrose tubing was found preferable to draining through the suture line. The drains usually were removed within 1 to 4 days.

The wound surfaces were dusted with sul fanilamide powder in some cases but only one of the surgeons felt this was sufficiently valuable to employ it routinely.

Casts or plaster splints were applied in many of the extremity wounds involving soft tissues only. After observing the breakdown of several of the unsplinted wounds near joints we were convinced that this should be practiced more widely.

POSTOPERATIVE MANAGEMENT

It appears to be necessary to retain stitches in a secondarily sutured wound longer than is usually necessary in a primarily sutured wound. In the absence of infection the stitches were generally removed in from 10 to 14 days.

Mobilization of joints and muscle training were practiced as early as tissue reaction permitted in many cases even before wounds were completely healed. Experience showed that wounds of the lower extremities, however healed far more promptly if patients were kept off their feet until healing was complete.

RESULTS

Percentage of healing For purposes of detailed study the healing of these wounds was classified as primary delayed primary or secondary. The meaning of primary healing is obvious. In certain wounds localized eversion of skin edges mild stitch reaction persistence of the drain sinus or delayed healing where cruciate incision corners had been brought together did not represent perfect primary healing. The end result though delayed a few days hardly differed from that in primary healing however. We called this "delayed primary" healing. Primary and

delayed primary healing together constituted satisfactory healing. When definite infection and separation or breakdown of the suture line occurred the result was called unsatisfactory. In so far as value of the operation of secondary suture was concerned¹

Calculated on the above basis the overall healing results in the series were as follows. For 1110 cases the healing was either primary or delayed primary (and therefore satisfactory) in 937 or 84.4 per cent. In 173 or 15.6 per cent the healing was unsatisfactory. In an unselected group of about half the cases (605 cases) the effect of an associated compound fracture was noted. Serious compound fractures were present in 110 of these. There were incomplete or chip fractures in 30 other cases. In 85 or 77.3 per cent of the 110 major fractures, the secondary closures healed satisfactorily. Although lower than the "satisfactory" percentage for the total we feel this is an acceptable showing for the large and complicated wounds of this type. Twenty three of these involved humerus or femur. 18 of the compound wounds healed satisfactorily. In this small group and only 5 were unsatisfactory. There were no cases of infection or gangrene leading to amputation attributable solely to the closure of the wound and no deaths. Secondary suturing of wounds complicated by compound fractures, then was found to be a safe and justifiable procedure.

Optimum time for secondary suture Table I shows the ratio of satisfactory to unsatisfactory healing after secondary suture by days from date of wounding. The ratio of virtually 10:1 for cases operated upon the 6th day after wounding is the best showing for any of the larger groups. After the 6th day the ratio becomes definitely less favorable. Since the delay in debridement of the wounds averaged nearly 24 hours, the choice of 5 days as the optimum time from debridement to secondary suture appears to be vindicated statistically in this series of cases.

Choice of anesthesia in secondary suture Local anesthesia was used in 243 cases with satisfactory healing in 215 or 88.4 per cent unsatisfactory in 28 or 11.6 per cent. General

¹In all the tables in this report, the figures refer to cases and not to individual wounds. Where there were multiple wounds, if only one broke down, the case was labeled "satisfactory."

anesthesia was used in 867 cases with satisfactory results in 722 or 83.3 per cent unsatisfactory in 145 or 16.7 per cent. Local novocain was used generally in the smaller wounds and only where there was no obvious sepsis. Keeping this method of selection in mind it is clear that in this series the use of infiltration anesthesia did not increase the postoperative rate of infection or adversely affect the percentage of satisfactory healing. We know of no instance of significant wound infection attributable solely to the use of local anesthesia in the closure.

Disposition. The figures for disposition after secondary suture in this hospital were available for 1204 patients as follows. There was a salvage rate of approximately 72 per cent of the men for General Service within an average time of only 6 weeks after wounding. The disposition of a great majority of the 18.1 per cent discharged for evacuation to the Zone of the Interior (United States) was determined by the presence of fractures, nerve injuries, amputations or other conditions not directly affecting the healing of their wounds. A higher percentage of the Limited Service cases were so reclassified chiefly because of wound disability but other conditions or complications also dictated this disposition in many cases.

OBSERVATIONS

We feel that the healing results obtained in this large series of war wounds can be improved with more experience. Limitations as well as possibilities of secondary suture have been learned. Some of the older or slightly infected wounds might have healed better after application of hot compresses or antiseptic dressings for a few days before suturing. The more experienced use of the various plastic surgical maneuvers to obtain approximation of skin edges without tension, more thorough splinting of wounds near joints, and enforced bed rest during healing of leg wounds all should increase the percentage of satisfactory results. As noted above (2) British Army surgeons found that the local application of penicillin to the wounds increased their ratio of successful healing after secondary suture. They did not have a comparable series of wound cases with systemic penicillin treatment but showed

TABLE I—HEALING RESULTS BY DAYS FROM WOUNDING TO SECONDARY SUTURE—FIFTY CASES

Interval in days	Total cases	Satisfactory	Unsatisfactory	Ratio	
				Satisf.	Unsatisf.
3	8	18			
4	9	80	11	8.8

14	1	7	5	4	
5 or more	13	28		2.8	

that wound infection sometimes developed despite intramuscular penicillin in usual doses. Further reports may clarify this subject.

Secondary suturing may be applied in peace-time traumatic surgery. The majority of such wounds, whether due to vehicle and industrial accidents or injury by firearms, explosives or other means, will prove amenable to immediate primary suture after thorough débridement. In the light of present knowledge, the administration of penicillin systemically would be indicated in all but minor wounds. A few wounds with excessive contamination, marked tissue destruction or prolonged time lag between injury and treatment will be more safely handled, however, by delayed suture. We would suggest culturing a wound of this type at the time of débridement. Sulfanilamide or penicillin¹ could be applied topically if the surgeon desired and an occlusive dressing applied. The first change of this dressing should be made in the operating room on the fourth or fifth day. If the wound appeared grossly clean and the first culture had grown no hemolytic streptococcus, secondary suture would be indicated at that time. If however the wound appeared septic

¹Some British Army surgeons favor penicillin-sulfathiazole powder for this use and treat the wound surface thoroughly.

or the culture revealed hemolytic streptococcus suture should be deferred for at least 2 days. Wet dressings perhaps with penicillin solution, should then be applied frequently until the wound becomes sufficiently clean to tolerate suturing. Such a routine should result in satisfactory healing in a very high percentage of cases.

SUMMARY

The results of secondary suturing of a series of wounds at an overseas General Hospital during World War II have been analyzed.

In 937 84.4 per cent, of 1110 cases, satisfactory healing was obtained as a result of this procedure.

It was found to be safe and generally satisfactory to suture secondarily those wounds associated with compound fractures.

Details of technique and management related to secondary suture are discussed.

It was possible to return 71.9 per cent of the men to general service 10.0 per cent were reclassified to limited service and 18.1 per cent were discharged from this hospital for evacuation to the Zone of Interior.

The application of this method of handling to certain peacetime wounds is recommended.

POSTCAVAL URETER, WITH DESCRIPTION OF A NEW OPERATION FOR ITS CORRECTION

OSWALD S LOWSLEY A B M.D. F.A.C.S. F.I.C.S. New York, New York

THE location of the right ureter behind the vena cava instead of overlying it, is a very rare anomaly, only 33 cases having been reported in medical literature to date. Even rarer is corrective surgical treatment of the condition only 4 such attempts having been reported previous to the one presented here.¹

In the present case a new operation was utilized which appears to have merit. It will therefore be described in detail.

REVIEW OF THE LITERATURE

Hochstetter, in 1892, was the first to describe a case of postcaval ureter in man this was in an infant a few weeks old and was discovered during routine dissection.

Pick and Anson tabulated 28 cases up to 1940 including one of their own. Five more have been added since one each by Harbach (1940) Harrill (1941) DeCarlo (1941) Gruenwald and Surks (1943) and Wilson and Herzlich (1944). The author's case makes the thirty fourth to be reported.²

Of these 34 cases 22 were diagnosed at post mortem examination or laboratory dissection 11 (including ours) at operation, and only 1 before operation.

All but 3 of the 34 patients were adults. Of these 3 cases, all discovered at routine dissection, one was in a stillborn infant, another in an infant a few weeks old and the third in a year old child.

Twenty five were males 7 were females and in 2 cases the sex was not given. It has

been suggested that the fact that males outnumber females by more than 3 to 1 in the reported cases may be accounted for by the greater number of male bodies that come to the dissection room and the postmortem table (where a majority of these cases were discovered). Of the 11 patients operated upon 7 were males and 4 females. Although a small group, this would seem to bear out the belief that the anomaly is more common in males.

Postcaval ureter may take several forms. The most common form is unilateral persistence of the posterior cardinal vein (observed on the right side only) the postrenal segment of this vein forming the postcava. Most of the reported cases are of this type. In 5 cases (Rotter Uebelhoefer Adachi 2, and Harrill) there was double postrenal vena cava, one on the right and one on the left side the ureter passing behind the corresponding vein. In only 1 case (Gladstone 1905) was there bilateral involvement. This case a stillborn acardiac infant, showed bilateral postcaval ureters (double postrenal vena cava, one on each side of the aorta with each ureter passing behind its respective vein).

EMBRYOLOGICAL CONSIDERATIONS

Present day opinion unanimously ascribes the anomaly to the embryonic vascular system rather than the urinary. Faulty development of the inferior vena cava and not maldevelopment of the ureter is the etiological factor responsible. In most of the reported cases the preureteric vena cava was associated with other anomalies of the retroperitoneal veins.

All later attempts at explaining the origin of anomalous retroperitoneal veins are based on the embryological work of McClure and Butler (1925) and Gruenwald (1938). Randall and Campbell Pick and Anson and Gruenwald and Surks have gone thoroughly into the embryology of postcaval ureter and the reader is referred to their papers.

From the Department of Urology (James Buchanan Brady Foundation) of the New York Hospital.

The necessary funds for this study were furnished by the Alfred Busiel Research Fund.

Commander Moody of the U.S.N. Hospital at St. Albans, N.Y. has notified the author of a sixth patient operated upon by him recently. He severed the ureter and made an end-to-end anastomosis over the vena cava.

Since this article was submitted, an additional case has been reported by Doctors L. F. Greene and W. M. Kearns of the Mayo Clinic. This was the second case in which the diagnosis was made before operation and the fifth case in which plastic repair was done. The ureter was severed and anastomosed in its upper portion.

Briefly, in the development of the embryo three bilaterally symmetrical pairs of veins appear in the lumbar region the posterior cardinals (lateral) the subcardinals (ventral) and the supracardinals (dorsal). Numerous anastomoses between these form venous rings. Quoting from Pick and Anson

"During fetal life the permanent kidney (metanephros) having developed in the pelvis, ascends to the upper lumbar level, passing through a ring of venous channels (perimetanephric or periureteral ring). The ventral limb of the ring is formed by the lumbar division of the postcardinal vein and the subcardino-postcardinal anastomosis (McClure and Butler) and sacrocardinal vein according to Gruenwald. The dorsal limb is a derivative of the lumbar division of the supracardinal vein and the subcardino-supracardinal anastomosis (McClure and Butler) or sacrocardinal vein of Gruenwald."

"Normally the postrenal portion of the inferior vena cava arises from the dorsal limb of the perimetanephric ring, the ureter thereby being placed in an antecaval position. But, in the anomalous arrangement of the ureter and vessel, one of the following developmental alterations occurs: (1) the ventral rather than the dorsal limb persists, the ureter then being postcaval; (2) the dorsal limb fails to arise at all—with similar results; (3) both limbs are present and persistent—the ureter passing between the cavae."

Most writers on the genesis of this anomaly agree that it forms from that limb of the embryonic perimetanephric ring which normally degenerates, that is, according to McClure and Butler the cardinal vein. However two later writers (Gruenwald and Surks) after going very extensively into the embryology express the opinion that the preureteric vena cava is a derivative of the subcardinal rather than the cardinal vein.

SYMPTOMATOLOGY

Symptoms, when present, are those of ureteral obstruction. The condition may be present throughout life however without causing symptoms.

Examination of most of the kidneys in adults showed hydroureter and in varying degrees, hydronephrosis and pyonephrosis. Stone formation was an occasional accompani-

None of the 3 cases in infants showed

of obstruction

Hydronephrosis may be sure exerted by the vena ca

pres-
nder

lying ureter, or by kinking or stricture due to the anomalous course of the duct. Uebelhoefer states that in certain cases the constriction may be due to the right ovarian vein crossing the postcaval ureter.

In our own case the symptomatology consisted of dull backache high up between the shoulder blades of 3 weeks duration accompanied by hematuria on two occasions severe headache at night and intermittent burning on micturition.

DIAGNOSIS

In only 1 of the reported cases (Harrill's) was the diagnosis made preoperatively—a not extraordinary fact perhaps, when one considers the extreme rarity of the anomaly. Cognizance on the part of the examiner that the condition may exist would appear to be a most important factor in preoperative diagnosis since the x ray findings are quite distinctive.

In Harrill's case the clinical picture was that of obstruction. Bilateral stereoscopic pyeloureterograms revealed a hydronephrotic right kidney with an elongated pelvis. From the preteropelvic junction the ureter curved upward in a wide arc toward the midline then downward toward the right side after which it continued downward in a normal course. As an important aid in diagnosis this author suggests a complete series of stereoscopic roentgenograms taken in the anterior posterior and oblique positions. He states "When viewed stereoscopically the radius of curvature should be great enough to include a structure having the diameter and position of the vena cava."

Another distinctive x ray finding that has been pointed out is the peculiar position that the ureter takes to the spinal column when seen in a roentgenogram which shows the spine fall away from the normal position. In

eyond the winding

bo

Fig. 1 Condition before operation. Right kidney in low position, ureter passes behind vena cava, and this portion of ureter is constricted. Left kidney is functionless. 2 Incision to expose right kidney and upper part of ureter. 3 Kidney exposed. Upper part of ureter and renal pelvis greatly dilated. Ureter being freed toward vena cava at point where it passes under the vein. Ureter constricted at this point (indicated by dotted line).

shaped curve with the convexity directed superomedially. The roentgenograms in our case showed the right ureter to be very near

the midline of the spinal column. This patient had a left kidney shadow and a left ureteral orifice in the bladder, but the ureter could not

be catheterized nor was there any evidence of shadow casting material in this region in the intravenous urogram.

In most of the reported cases in which operation was done the clinical picture was that of ureteral obstruction with the cause of the obstruction remaining obscure. It is our opinion that postcaval ureter should be considered in all cases of hydronephrosis of obscure etiology, especially when the roentgenograms show a double right-angled kink with the ureter below this point displaced toward the midline.

TREATMENT

Corrective surgery—namely transference of the ureter from its anomalous position behind the vena cava to a more nearly normal site—is the procedure of choice. In some cases however the kidney will be found so badly damaged that nephrectomy becomes necessary.

A review of the 11 cases in the literature in which operation was done discloses that nephrectomy was performed in 6, nephrothoromy alone in 1, and corrective procedures in 4 (Kimbrough 1932; Uebelhoefer 1936; May 1938; Harrill 1940). In all 4 cases the ureter was divided, disengaged from the retroperitoneal tissues, drawn from behind the vena cava, placed in normal position, and anastomosed. Harrill's was the only case in which the division and anastomosis were above the ureteropelvic junction. The results in all 4 cases were reported as good.

In our own case because it was deemed advisable to preserve the intrinsic nerve supply the ureter was severed at its point of entry into the bladder wall, removed from behind the vena cava and placed in normal position and its end reimplanted in the bladder wall as described below.

The past history was unimportant.

The right kidney could be felt on palpation. The urine showed 10 per cent pus and an occasional red blood cell; the prostatic secretion showed 20 per cent pus. Otherwise the physical examination, including rectal examination, was essentially negative.

A complete urological investigation was done. Cystoscopy revealed trabeculation in the region of the left ureteral orifice and considerable edema of the vesical orifice. A leaf catheter No. 6-F passed to the kidney pelvis on the right side, but a No. 4-F catheter could be passed only about 5 centimeters on the left side. The x-ray films showed a small kidney shadow, high in position, on the left side and a kidney shadow, large in size and low in position on the right side. There was a large moth-eaten shadow opposite the transverse process of the third and fourth lumbar vertebrae and another just opposite the fifth lumbar vertebra; these were thought to be calcified lymph glands. The right pyelonephrogram showed a greatly dilated kidney pelvis and a right-angled kink of the ureter. None of the shadow casting material entered the left side. Excretory urograms at 5, 10, and 25 minutes were made. These showed prompt function on the right side and no evidence of function on the left.

The impression was that the patient had a dead left kidney and a right hydronephrosis with a kink of the ureter.

Two days after admission the right kidney was exposed under spinal anesthesia.

OPERATION

Fig. 2 1 A nephrostomy tube has been placed in the kidney pelvis and fixed in position by ribbon gut. Nephropexy is being carried out by drawing Gerota's fascia around the kidney and suturing it to the quadratus lumborum muscle with ribbon gut. 2, Upper portion of wound partly closed. Incision extended downward and across rectus muscle to expose middle and lower portion of ureter. 3, Entire ureter has been exposed. Dividing ureter close to its insertion in bladder.

The patient was then placed on his back and the lower end of the wound extended down the right border of the rectus muscle and

across its lower end to the midline. The incision was deepened to but not into the peritoneum which was bluntly dissected free and

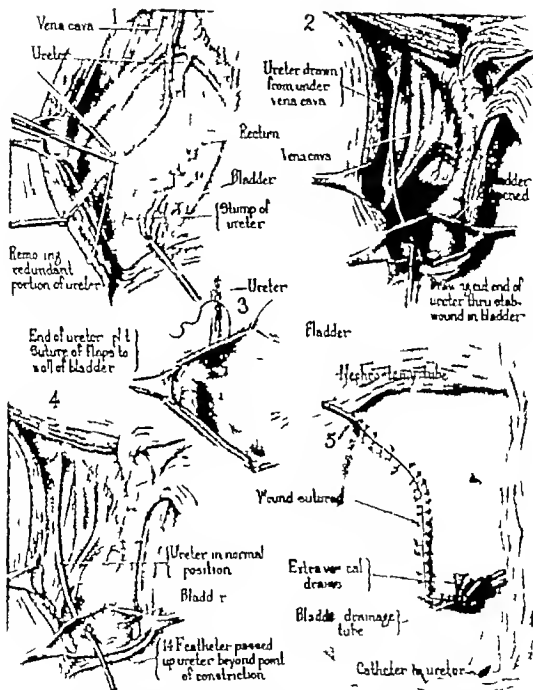

Fig. 3. Removing redundant portion of ureter. 2. Ureter has been drawn from under vena cava cut end being drawn through stab wound in bladder. 3. Cut end of ureter has been split flaps being sutured to bladder wall. 4. Ureter reimplemented in bladder. No. 4 F catheter passed up ureter beyond point of constriction. 5. Entire wound has been closed. A drainage tube has been placed in the bladder and its extravesical drains down to the site of implantation of the ureter. No. 4 F catheter from ureter shows emerging with other drains.

the vena cava exposed. The ureter was identified to it under it, and passing down mesially across the left iliac vein just before it

joined the right iliac to form the vena cava. The entire lower end of the ureter was isolated and because it was thought advis-

Fig. 4. Pyelogram and pyeloureterogram after the injection of 25 cubic centimeters of skiodan.

able to preserve the intrinsic nerve supply of the ureter it was tied off at its insertion into the bladder wall. The ureter was then drawn from beneath the vena cava and brought over the vein the bladder was opened, and the ureter reimplanted into its superior posterior wall and fixed in position with a chromic catgut No. 00 suture about 6 centimeters of the lower end of the ureter being excised to allow it to be straight, without tension.

A No. 14 F splinting soft rubber catheter was inserted into the ureter beyond its narrowed point and brought out through the bladder incision and fixed to the skin of the lower end of the wound. A double suction tube was inserted into the bladder which was closed and the tube attached to the fascia in the lower angle of the wound. Four grams of sulfanilamide were distributed throughout the wound. A drain was inserted to the opening in the bladder and another drain to the anastomosis of the ureter and the bladder.

The wound was closed in layers and the patient returned to his room in good condition.

Postoperative course. After the removal of the splinting catheter the nephrostomy wound continued to drain. Attempts to insert a catheter by means of the cystoscope were un-

availing and 6 weeks after the first operation it was decided that the patient should again be operated upon.

The bladder was exposed by a Pfannenstiel incision extended upward on the right side. It was opened and a No. 10-F catheter was finally passed into the reimplanted ureter after incising the ureter about 3 centimeters above the bladder implantation at which point there was found to be a tight stricture. The catheter was inserted into the kidney pelvis and out through the urethra and fixed in position. The ureter was closed by 3 interrupted mattress sutures of No. 0000 catgut. The wound was closed in layers without a drainage tube in the bladder and the patient was returned to his room in good condition. The No. 10-F ureteral catheter thus passed from the kidney pelvis through the bladder and the urethra.

Subsequently a discharging sinus required still another operation at which time it was found that an abscess had developed about the lower end of the ureter and a considerable portion of the duct had sloughed off. The lower end of the ureter was, therefore, implanted into the skin.

The patient has made an uneventful recovery from this final operation. The catheter

passes to a bag strapped to his leg, and he goes about his work handling this apparatus very well. Indeed

SUMMARY

1. Postcaval ureter is a very rare anomaly, the present case being the thirty-fourth to be reported in medical literature.

2. This is an anomaly of the embryonic vascular system rather than the urinary, being due to faulty development of the inferior vena cava. The pre-ureteric vena cava is usually associated with other anomalies of the retroperitoneal veins.

3. Of the 34 reported cases, 22 were discovered at postmortem examination or laparotomy dissection, 11 (including ours) at operation, and only 1 preoperatively.

4. Postcaval ureter may be present throughout life without producing symptoms. Symptoms when present are those of ureteral obstruction, which may be produced by pressure exerted by the vena cava upon the underling ureter, or by kinking or stricture due to the anomalous course of the ureter.

5. Stereoscopic roentgenogram taken in the anterior, posterior, and oblique positions aid in the diagnosis. The x-ray appearances are distinctive in the following respects: (1) In an oblique film the portion of the ureter dorsal to the vena cava will impinge against the lower lumbar spine, whereas the normally situated ureter will fall away from it. (2) The postcavally placed ureter is always displaced toward, to, or even beyond the midline of the body. The ureter winding around the vessel forms a sickle-shaped curve with the convexity directed supermedially.

6. Severe damage to the kidney may require nephrectomy. Otherwise corrective surgery—namely, transection of the ureter from behind the vena cava to its normal position in front of the vessel—is the treatment of choice.

7. Only 4 cases treated by corrective surgery have been reported previous to our own.

In 3 of these, the ureter was divided and anastomosed in its upper portion; in 1 the division and anastomosis were above the ureteropelvic junction.

8. The operation described here aims at the preservation of the ureter's intrinsic nerve supply while correcting the anomaly. The ureter is severed at its point of entry into the bladder wall, removed from behind the vena cava, placed in normal position, and its end reimplanted into the bladder wall.

CONCLUSIONS

1. Postcaval ureter should be considered in all cases of hydronephrosis of obscure etiology, particularly when the roentgenograms show a double right-angled kink with the ureter below this point displaced toward the midline.

2. Division of the ureter at its vesical end and reimplantation into the bladder wall is preferable to division and anastomosis higher up because (1) the peristaltic wave is not interfered with, and (2) stricture at the site of repair is less likely to occur.

TOPICAL PENICILLIN TREATMENT OF ESTABLISHED INFECTION IN COMPOUND FRACTURE WOUNDS

JOSEPH WEINBERG M.D., F.A.C.S. Major M.C., A.U.S. Van Nuys California

REPORTS concerning the use of parenteral and local penicillin therapy in the treatment of established suppurative infections in compound fracture wounds have been generally pessimistic. The poor results with parenteral therapy are explained by the failure of all but a small proportion of the administered penicillin to permeate the edematous indurated zone of tissue which forms a wall about the site of infection. The principal advantage of local therapy is the high concentration of penicillin which is maintained at the site of infection. The chief objection to this method has been the difficulty of instilling the penicillin solution at frequent enough intervals and with sufficiently sterile technique to obtain the maximum benefits. The purpose of this report is to describe a method of topical penicillin therapy which overcomes these difficulties and which has proved itself to be highly effective in a group of cases which had been refractory to previous treatment by other methods.

The cases in which this method was used were of compound fracture wounds in which established infection had existed for periods ranging from $2\frac{1}{4}$ to 27 months before starting the method to be described in which penicillin jelly, a mixture of penicillin with lubricating jelly is applied to the surface of the wound. For the most part, the wounds were produced by shrapnel machine gun fire and rifle fire with resulting extensive destruction of soft tissue and bone. All of these cases had been refractory or had shown little progress with previous treatment, and have shown a greatly increased rate of healing with the change to topical application of penicillin jelly. In some instances this response has been spectacular healing taking place within a few weeks in wounds which were resistant to other methods of treatment for a period of months.

The average time between wounding and the start of penicillin jelly treatment in the 28 patients comprising this series was 10.34 months. The average time between the initiation of penicillin jelly therapy and complete healing in 23 of the 28 patients was 1.16 months. There were two failures with the penicillin jelly treatment in the sense that the soft tissue wounds failed to heal completely. Three patients remain unhealed at the time of this report but their progress indicates that healing will be complete within a reasonable period without changing the type of therapy. These wounds had existed for an average period of 16 months prior to penicillin jelly treatment, and showed satisfactory progress but incomplete healing after an average period of 4 months of this therapy.¹

RATIONALE OF TOPICAL PENICILLIN THERAPY

The pathologic process at work in old compound fracture wounds is a vicious circle in which localized infection of bone usually goes on to sequestration. The infected bone and the sequestra act as local sources for further infection of bone and surrounding soft tissues which in turn causes further degeneration and sequestration. The cycle will continue as long as sequestra are present or suppuration persists.

The aim of the penicillin treatment is to break up the vicious circle by eliminating or minimizing the infection in the wound while awaiting sequestration and to arrest infection after sequestra are eliminated. The penicillin mixture to be described when retained in surface contact with the suppurating area in sufficiently high concentration acts as a strong deterrent to infection and when used in conjunction with adequate drainage elimination of sequestra, aseptic technique and general supportive measures has proved to be

¹Observation of these patients as interrupted by the transfer of the author to another hospital.

Fig. 2. Case 2. a, Appearance of tibia, June 9, 1944. The degenerated fragment now shows definite evidence of regeneration, with callus bridging the former gap between the fragment and the shaft of the tibia.

far more effective in promoting healing than has any other method previously used by us in this type of disease.

TECHNIQUE OF TOPICAL APPLICATION OF PENICILLIN

A mixture of penicillin and lubricating jelly in the proportion of 1000 units per cubic centimeter is applied directly to the wound at each dressing the standard United States Army lubricating jelly containing phenylmercuric acetate 1:6000 glycerite of tragacanth quince seed and aromatics being used.¹ This vehicle which is water soluble releases penicillin more readily than would an ointment base and its consistency assures its contact with the wound for several days. The acidity of the lubricating jelly which is in the vicinity of pH 4.4 apparently does not inhibit the action of the penicillin. The peni-

cillin jelly is prepared by mixing 1 cubic centimeter of normal saline solution containing 20,000 units of penicillin with 19 cubic centimeters of autoclaved lubricating jelly in a sterile medicine glass. This mixture is prepared just before beginning the wound dressings and is usually sufficient for 6 to 8 dressings. The wound is cleansed with hydrogen peroxide followed by normal saline solution, immediately preceding the application of the penicillin jelly. Hydrogen peroxide appears to be a valuable adjunct in the treatment and there is no evidence that it lessens the effectiveness of the penicillin when it is used in this manner. Normal saline solution was used alone in some of the earlier treatments and the results were less satisfactory.

Lubricating jelly is in itself a bacteriostatic agent and probably enhances the value of penicillin. An opportunity to compare the effects of penicillin jelly and lubricating jelly without penicillin was afforded in a patient

¹The preparations of lubricating jelly on the general market should be tested for pH and for possible inhibiting action on penicillin before they are used as described here.

Fig. 1 c, Filling of wound defect by blood clot. The clot was infected with penicillin solution and was overlaid with penicillin jelly to prevent infection and thus encourage organization. d, Final wound healing following split thickness skin grafting of the surface of the organized blood clot.

with wounds on the medial and lateral aspects of the leg. Penicillin jelly was used on the severe medial wound and the standard lubricating jelly was used on the relatively minor lateral wound. After 2 weeks of treatment the medial wound was completely healed while the lateral wound showed only moderate improvement. This and other observations offered convincing evidence that the beneficial effects of penicillin jelly are not due to lubricating jelly alone.

Dressings were made at intervals varying from daily to every fifth day during the experimental phase. In most instances there was evidence of bacterial growth if the dressing interval extended beyond the third day. The most favorable response was with dressings daily or every other day, and since the wounds did just as well with dressings every other day that interval is now used routinely. The only exception is in the first few days of the treatment when suppuration is profuse. At that time it is well to apply the penicillin

mixture daily, its efficacy being lessened by the mixture with pus. After several days, often within 2 days, the wound becomes so dry that the gauze dressing is found to be fixed firmly to the wound at each dressing. This adherence is due to the drying action of the lubricating jelly and to the lessened purulent secretion.

Strict surgical technique is observed in performing the dressing. This is especially important in a large ward with a variety of septic wounds where cross-infection with organisms of high virulence is a constant danger. The dressers wear caps, face masks, and gowns; the patient's mouth is away from the wound, and the dressings are done in a private room whenever possible in order to avoid the dust of the ward. Casts are changed if they become soiled with exudate. Instrument technique is used throughout.

Treatment with penicillin jelly has distinct advantages over the method of instillation of penicillin solution through tubes. The latter

Casts are changed if they become soiled with exudate. Instrument technique is used throughout.

Treatment with penicillin jelly has distinct advantages over the method of instillation of penicillin solution through tubes. The latter

Fig. 2. Case 20. a, Perforating wound of lower third of femur with depression due to loss of soft tissue and bone. b, Appearance of soft tissue wound 20 months after wound ing. Exposed bone is partially covered with suppurated g

granulation tissue. c, Treatment of the wound with penicillin jelly for 27 days followed by split thickness skin grafting of exposed bone surface has resulted in complete healing.

method was used in earlier cases, but was discontinued because of the difficulties encountered in administering the treatment. The chief objection was that the instillations were often made by unskilled personnel and it was impossible to prevent micro-organisms from entering the wounds through the tubes due to errors in handling syringes and in managing the ends of the tubes. Three of 10 wounds thus treated became contaminated with *Bacillus pyocyaneus* within a period of 2 days. Another objection was the work entailed in making the instillations at intervals of 3 hours in a large number of cases.

BACTERIOLOGY

Bacteriological studies were made to determine the organisms present in the wounds and to determine the resistance of the infecting bacteria to various concentrations of penicillin. The finding of especial interest was the tendency of organisms which persisted in the wounds to show a progressively increasing resistance to the action of penicillin. This was particularly noticeable with *Bacillus proteus*. With the beginning of treatment several

wounds showed cultures of *Bacillus proteus* which were completely inhibited by concentrations of penicillin as low as 25 units per cubic centimeter. Cultures taken after 2 weeks showed *Bacillus proteus* from the same wounds to be completely resistant to concentrations of 1000 units per cubic centimeter. For the most part *Bacillus proteus* was resistant from the beginning to concentrations of 250 units per cubic centimeter or higher. This was also the case with *Bacillus pyocyaneus*. *Staphylococcus* was susceptible to low concentrations of penicillin in most instances. Twelve cultures showed complete inhibition with 25 units or less; 1 was susceptible to 100 units and 1 to 250 units. There was little opportunity to check variations of susceptibility in this organism during penicillin therapy as the *staphylococcus* usually disappeared after a few days of treatment. Organisms which showed complete resistance to concentrations of 1000 units of penicillin per cubic centimeter including *Bacillus proteus* and *Bacillus pyocyaneus*, did not prove to be troublesome contaminants, and usually disappeared from the wounds within a few

weeks. There has been an unusually high incidence of *Bacillus proteus* in this group of patients. This may be explained by the fact that a majority were previously treated with penicillin intramuscularly or with sulfonamides and the resistant *proteus bacillus* remained in the wounds after other organisms had been made to disappear.

Suppuration has been controlled in all of the wounds treated by this method regardless of types of bacteria present so it is not considered essential to make detailed bacteriological studies except for investigation purposes.

CLINICAL AND PATHOLOGICAL FEATURES OF WOUNDS TREATED

The 28 cases of compound fractures with long standing wound infection which comprise this series had been refractory or were slow in response to treatment by other methods before beginning the treatment with penicillin jelly. Wounds of short duration and wounds which were near completion of healing when the penicillin jelly treatment was started are not included in this report. The injuries treated involved the following bones:

	cases
Tibia, or tibia and fibula	16
Tarsal and metatarsal bones	5
Femur including hip joint	3
Shoulder joint, involving head of humerus	2
Shaft of humerus	
Sacrum, complicated by pelvic abscess	1

The local pathologic changes which were considered most significant in influencing the course of the disease were suppurative cellulitis, edema of varying degree, localized degeneration and necrosis of bone with or without sequestration, degeneration and necrosis of the soft tissues and impairment of regional circulation due to direct injury, edema, thrombosis and trophic changes. In addition there are to be considered the variables of the injuring force and the depth and irregularity of the wounds. As stated previously the types of bacteria did not appear appreciably to influence the course of the healing.

INFLUENCE OF BONE SEQUESTRATION ON WOUND HEALING

The course of wound healing was influenced as much by the proper removal of sequestra as

Fig. 3. Case 21. a, left, Appearance of femur 7 months after refracture. An intractable draining wound persisted throughout this period and was thought to be responsible for lack of tendency to union. b Secondary closure following 31 days of penicillin jelly treatment resulted in permanent healing of the soft tissue wound and union of the fractured femur.

by any other factor. Removal of large sequestered fragments was delayed as long as there appeared to remain a possibility of revascularization. This has caused a delay in healing in some cases because of the eventual complete necrosis of the fragment but the value of the segment if it did revascularize more than compensated for the delay in healing time. The following case illustrates this point.

CASE 22. Revascularization of devitalized bone segment (Fig. 1)

Patient, aged 30 years, was wounded in combat by shrapnel early in February 1944 sustaining a severe

Fig. 4. Case 18. a, left, Perforating fracture of sacrum with bullet lodged in pelvis. Multiple operations for drainage over period of 13 months, and removal of the bullet were unsuccessful in arresting suppurative infection of pelvis. b, Location of anus tract, originating in the pelvis and emerging over the left greater trochanter.

compound comminuted fracture of the middle third of the tibia. Early treatment included débridement sulfadiazine orally and closed cast which was continued until June 12, 1944, at which time it was decided not to remove a large devitalized segment of cortical bone because of the certainty of weakening the tibia by its removal.

The wound was then treated for several months with various topical medications including sulfathiazole ointment azochloramide solution and aqueous solution of penicillin in the strength of 1000 units per cubic centimeter. The wound remained indolent with little roentgenological evidence of bone regeneration in the devitalized segment of tibia.

Penicillin jelly treatment was instituted December 11, 1944, following which there was prompt epithelialization of the wound together with evidence of progressive regeneration in the devitalized bone and union of the fracture.

Small spicules of sequestered bone became detached from the regenerating cortical fragment from time to time and operation was performed on March 14, 1945 for removal of devitalized bone from the surface of the fragment. The wound defect was allowed to fill with blood. It was not possible to close the soft tissues over the defect. The blood clot which formed was treated with injections of several drops of penicillin in normal saline solution 1000 units per cubic centimeter on the first third and fifth days following operation. Intramuscular injections of penicillin, 20,000 units every 3 hours were given for a period of 15 days beginning 2 days before operation. The blood clot was covered with penicillin jelly.

The clot became organized in 3 weeks and was then covered with split thickness skin grafts. Sur-

with contrast medium show the principal pocket in the left iliac region within the pelvis. The abscess, which had persisted for 30 months, became healed after 4 days of treatment with penicillin jelly injected into the tract every other day. Observation for 6 months following healing shows no evidence of recurrence of infection.

face healing was complete on April 30, 1945. Later x-ray examinations showed satisfactory union of the revascularized segment with the shaft of the tibia.

The importance of carefully planning the operation of sequestrectomy cannot be overemphasized. The sequestrum should be accurately localized beforehand by roentgenographic study with views in addition to the standard anteroposterior and lateral whenever necessary. The incision is planned to permit a direct approach to the necrosed bone with a minimum of disturbance to living bone and soft tissues. In some of our patients it was necessary to make the incision through normal skin away from the wound to accomplish this. In 2 instances in this series, wound healing was unnecessarily delayed because of failure to remove all of the sequestra present. In these cases the operative incisions were inadequate for proper exposure of the diseased area.

All operations of sequestrectomy as well as other types of revision operations are preceded and followed by several days of intramuscular penicillin therapy.

The particular advantage of topical treatment with penicillin jelly in wounds harboring sequestra is that further necrosis of soft tissue and bone is held in check by the inhibiting effect of the penicillin on the infection thus

breaking the vicious circle described previously

PRESENCE OF DEGENERATED BONE

The difficulties of management of degenerated bone are much the same as with sequestra. Degenerated bone causes greater delay than does sequestered bone because it is impossible in most instances to determine whether the degenerated bone will revascularize or will go on to necrosis. Extensive loss of bone makes it necessary to conserve as much osseous tissue as possible therefore one must guard against sacrificing bone in which there remains any possibility of revascularization. The point is stressed that, although early healing is desirable, it is not so important that it should be attained through the sacrifice of valuable fragments

EXCAVATED WOUNDS

Depressed wounds due to loss of bone substance especially those in which bone remains exposed, are definitely a cause of delayed healing. This is noteworthy in shoulder wounds with partial or complete loss of the head of the humerus in which the wound is held open by the surrounding bony prominences. Two such cases in which healing was making little progress with sulfathiazole ointment, azochloramide instillations and penicillin instillations used successively showed a remarkably rapid response to penicillin jelly

CASE 25 Healing of shoulder defect

Patient aged 20 years was wounded in action on June 24 1944 sustaining a mortar shell injury with a severe compound fracture-dislocation of the head and neck of the left humerus, together with other injuries

The wound was debrided and an Orr dressing in shoulder spica cast was applied. He was evacuated to the United States after several months arriving at this hospital September 5 1944. Removal of the cast several days after his arrival here revealed a deep cone shaped wound on the prominence of the shoulder measuring 5 centimeters in diameter and 6 centimeters in depth.

Closed cast treatment was continued until October 18 1944 after which time the wound was dressed through a fenestration with hydrogen peroxide cleansing and 5 per cent sulfathiazole ointment. Healing progressed slowly and on November 16 the local therapy was changed to instillations of

aqueous solution of penicillin 500 units per cubic centimeter through a small caliber soft rubber tube every 4 hours. Some improvement was noted with this change in treatment, but the method was cumbersome and there was evidence of wound contamination apparently due to faulty technique in making the instillations.

Penicillin jelly treatment was started December 11 1944. Improvement was noticed within a few days and the wound which had remained almost stationary at 2 centimeters in diameter and 3 centimeters in depth for some weeks previous to the use of penicillin jelly now healed rapidly and was completely closed on January 30 1945.

Arthrodesis of the shoulder was performed on April 12 1945 with primary healing of the surgical wound.

Healing by organization of blood clot was accomplished in 4 cases of tibial defect. Blood was permitted to fill the defect following sequestrectomy and saucerization of the bone. The resulting blood clot was injected with a few drops of a solution of 1000 units of penicillin per cubic centimeter of normal saline solution. The surface of the clot was protected by a dressing of penicillin jelly. Wounds treated in this manner showed gross evidence of organization of the blood clot 3 to 4 weeks after operation. In 2 instances the organizing clot was overlaid with split thickness skin grafts 4 weeks after operation. None of the clots liquefied or became infected, and there was only slight depression of the area on completion of healing. In the light of previous experience with organization of exposed blood clot it is reasonable to assume that penicillin played an important rôle in the healing in these cases (Fig 1, c and d).

CASE 14 Healing by organization of blood clot.

Patient, aged 27 years was injured by shrapnel in combat with the enemy October 26 1944 sustaining a severe compound comminuted fracture of the upper portion of the left tibia.

The wound was debrided within a few hours and was treated with sulfathiazole powder vaseline gauze and a circular cast from the toes to the upper thigh.

The dressing was not removed until he reached this hospital January 8 1945 at which time there was evidence of moderate suppuration with fragmentation of the tibia.

Operation of sequestrectomy and osteotomy was performed January 10 at which time several long splinters of necrosed bone were removed. Culture of the wound revealed *Bacillus proteus* which on

testing was inhibited by 250 units of penicillin per cubic centimeter. A large defect in the tibia and soft tissues 10 centimeters in length, 2.5 centimeters in width and 3 centimeters in depth was allowed to fill in with blood clot. Several drops of penicillin in normal saline solution, 1000 units per cubic centimeter, were injected into the blood clot on the first and third postoperative days. The surface of the clot was overlaid with a thin coating of penicillin jelly. The clot organized with moderate retraction, and was covered with split thickness skin grafts on February 7. All grafts were successful, and healing of the wound was complete on March 1, 1945.

EXTENSIVE LOSS OF SOFT TISSUE WITH EXPOSURE OF BONE

Exposed bone is a deterrent to wound healing because of its tendency to degeneration and necrosis as long as it remains uncovered even though infection is held in check. Therefore an effort is made to cover the exposed bone with soft tissue at the earliest favorable time. Good results have been obtained by placing split thickness skin grafts directly on bone after gross evidence of necrosis and infection has disappeared even though wound cultures remain positive. The skin-grafted surface is treated with compression dressings moistened every other day with normal saline solution containing 1000 units of penicillin per cubic centimeter and compression is maintained for a period of 8 to 10 days. This procedure was used in 5 cases in which an infected open wound had been present for from 6 to 28 months. All except 1 healed completely. The single case of failure was a tibial compound fracture wound which had remained open with bone exposed for 20 months following metal plating. There was no gross evidence of bone necrosis or suppurative infection following operation of skin grafting and it is probable that failure was due to inadequate circulation in the exposed bone.

CASE 20. Skin grafting of exposed bone surface following treatment with penicillin jelly (Fig. 2)

Patient, aged 21 years, was injured by shrapnel in overseas combat April 9, 1943, receiving a perforating wound of the distal third of the femur with loss of the patella.

Treatment prior to his arrival at this hospital April 8, 1944, consisted chiefly of blood transfusions and plasma infusions, penicillin intramuscularly, closed cast treatment, and two operations: sequestrectomy

Examination here disclosed a large open wound on the anterior of the lower third of the thigh with an irregular perforating wound of the femur. The wound was treated with sulfathiazole ointment dressings until October 17, at which time the bone was sauterized to encourage overgrowth of soft tissue.

Topical penicillin in normal saline solution every 4 hours was started November 6, 1944. Cultures at this time showed the presence of nonhemolytic *Staphylococcus albus* and *Bacillus proteus*. The profuse suppuration was lessened, but ingrowth of soft tissue over the large area of exposed femoral bone was negligible.

Penicillin jelly treatment was started December 15, 1944, and the suppuration subsided completely within 10 days. Split thickness skin grafts were applied over an area of exposed bone 5 centimeters in length and 2 centimeters in width on January 11, 1945. All of the grafts remained viable and the wound was completely healed on January 23, 1945.

Secondary wound closure by suturing was usually not possible because of the loss of bone substance and the loss of overlying soft tissues. Only 2 cases in the series were suitable for this procedure. One of these described in the following case history illustrates the favorable effect of the procedure on a fractured femur which had shown little tendency to unite before the wound was closed secondarily.

CASE 21. Secondary wound closure by suturing (Fig. 3)

Patient, aged 24 years, received a bullet wound November 24, 1943, which caused a fracture of the middle third of the left femur. He was treated in traction, followed by hip spica cast until May 30, 1944.

He refractured the femur June 17, 1944, while out of cast, and was admitted to this hospital 1 month later. Examination here disclosed a comminuted simple fracture of the middle third. The extremity was put in traction. An abscess formed in the soft tissues in the region of the fracture and this was drained August 22, 1944. His condition, which had been critical, improved rapidly following adequate drainage. However drainage continued unabated. A large femoral fragment showed evidence of advanced degeneration and showed little tendency to unite to the proximal and distal main fragments. The soft tissue wound was intractable to treatment with sulfathiazole ointment, and showed little response to instillations of azochloramide solution and penicillin solution used successively.

Penicillin jelly treatment was started December 12, 1944, and was continued until January 12, 1945. At that time the trough-shaped wound, measuring 15 centimeters in length and 2 centimeters in depth, showed no suppuration, and was epithelialized ex-

cept in its depth. Secondary closure of the wound was performed January 12, 1945. The wound remains completely healed after a period of 4 months and the femur shows evidence of increase in callus formation with apparent union.

INACCESSIBLE WOUNDS WITH SINUS TRACTS

There have been several cases of deep sinus tracts in which it was inadvisable to explore the depth of the wound by surgical operation. These patients were examined roentgenologically following injection of a radiopaque medium into the tracts through a soft rubber catheter after making certain that there was free exit for any substance injected. Following this examination to determine the extent of the pockets of infection, penicillin jelly was injected into the sinus tracts every other day. The merit of the use of penicillin jelly in these cases lies in the fact that it is apparently harmless when it is retained in the wound. One of the patients treated in this manner a pelvic abscess secondary to a bullet wound through the sacrum is of especial interest.

CASE 28. Healing of inaccessible wound with sinus tract (Fig. 4).

Patient aged 24 years received an accidental .45 caliber bullet wound on June 12, 1943, the bullet entering the left gluteal region, piercing the middle third of the sacrum, tearing segments of small bowel and sigmoid, and lodging in the pelvis. The intestine was repaired 2 hours later.

A large subpubic abscess was drained June 25, 1943, and a left retroperitoneal abscess was drained August 12, 1943.

A flexion deformity developed gradually in the left hip and the hip became ankylosed with destructive changes in the joint cartilage. The earlier drainage of the pelvic abscesses had resulted in a persistent sinus emerging in the left lower anterior abdominal wall. In November 1943 x-ray of the tract, with iodized oil as a contrast medium, showed ramifications extending toward the crest of the left ilium, the hip joint, and the ischium.

A total of 20,300,000 units of penicillin was given intramuscularly from February to August, 1944. Cultures of hemolytic streptococcus from the tract were reported during this period.

Exploratory surgical incision was made in the left hip region over the greater trochanter on March 22, 1944. There was no pus found in the hip joint. An abscess broke through the exploratory hip incision on April 5, 1944. A subsequent pelvic operation performed July 26, 1944, was unsuccessful in arresting the drainage from the sinus in the left hip region.

The patient was transferred to this hospital September 10, 1944. At that time all surface wounds

were closed except the sinus tract emerging at the left hip. Wound culture showed nonhemolytic *Staphylococcus albus*, nonhemolytic streptococcus, and *Bacillus proteus*. The bullet was removed from the pelvis November 30, 1944. There was no change in the drainage of pus from the sinus tract of the hip following this surgical procedure. No pus was seen in the vicinity of the bullet at the time of its removal.

X-ray examination following injection of the sinus tract with radiopaque medium showed essentially the same findings as those previously described with the exception that the abscess in the lower left pelvis was more clearly defined.

Injectations of penicillin jelly into the sinus tract were started January 16, 1945. The injections were made every other day through a No. 12 soft rubber catheter, 2 cubic centimeters of the jelly being instilled with very moderate pressure. The tract became completely closed on January 30, 1945, for the first time since the development of the sinus on March 22, 1944, and has now remained closed for a period of 6 months. The white blood cell count and temperature remain normal and the patient is completely well except for an almost complete ankylosis of the left hip joint.

It is possible that removal of the bullet played a part in the healing in this case but the fact that no communication was demonstrated between the bullet and the abscess at the time of operation and the fact that the purulent drainage which had continued for 6 weeks following operation ceased promptly after penicillin jelly instillations would argue for penicillin jelly being the major factor.

INFLUENCE OF GENERAL DISTURBANCES ON WOUND HEALING

General factors which should be given consideration are the state of body nutrition, the character and volume of blood, protein sufficiency, vitamin balance, and concurrent diseases. It is difficult or impossible to measure the degree of departure from normal with ordinary methods in most of these factors except when the departure from normal is extreme. Nevertheless, it must be accepted that such disturbances do exist in chronic suppurative infections and that they should be considered as factors in influencing healing.

Protein insufficiency is a constant accompaniment of prolonged severe suppuration and a high protein diet is important in helping to overcome this deficiency. This is especially important for the soldier returned from a distant outpost where some essential foods are

lacking and certain types of malnutrition are prevalent. Edema of the tissues in and around the wounds is interpreted as serious protein deficiency if circulatory cause can be ruled out. It has not been considered necessary to measure the proteins of the blood or to determine the albumin-globulin relationship except in patients with pronounced edema.

Vitamins which are known to be of importance in wound healing particularly vitamin C have been found to be low in most of the cases in this series. The need for this vitamin and vitamin B complex in greater quantities in those suffering from suppurative disease or in those who are undergoing wound healing has been satisfactorily demonstrated by research workers. The diet is supplemented with liberal amounts of orange juice and in addition to this a supplement of vitamin C is given intramuscularly if the patient shows a low vitamin C blood level. These include patients showing less than 0.8 milligram per 100 cubic centimeters of blood.

A continued low blood level that does not improve with transfusions and adequate diet is usually due to suppuration. In such cases attempt is made to control infection by removal of sequestra or improvement of drainage.

Optimum circulation in the injured part is maintained by proper elevation by application of warmth in cases of vascular injury and by bandaging and splinting in such a manner as to prevent unequal pressure with its consequent accumulation of venous blood in the region of the injury. In this connection the principles of supportive and compressive bandaging used in the treatment of varicose ulcers applies equally well to established compound fracture wounds of the leg.

Local and general physical conditioning of the patient is continued throughout the treatment except during periods immediately following major operations of sequestrectomy, drainage, or wound revision. Exercises are directed toward the conditioning of muscles in the affected extremity and muscles in general. This phase of therapy is especially important in patients whose wounds require months for healing.

SUMMARY

1. A method of topical application of penicillin in lubricating jelly in the treatment of established infection in compound fracture wounds is described. It has the advantage of maintaining high concentrations of penicillin in the area of the wound without the use of cumbersome technique or apparatus.

2. Evidence is presented of the effectiveness of this preparation in permeating the barriers in the zone of infection. This is in contrast to parenteral administration in which relatively small amounts of penicillin reach the area of suppuration.

3. Twenty-eight compound fracture wounds with established infection have been treated by this method. They had been refractory or slow in response to accepted methods of therapy for periods varying from 2 to 27 months, and all except 2 have shown a highly satisfactory response to treatment with penicillin jelly.

4. Delay in the healing of old infected compound fracture wounds is most frequently due to the presence of necrosed bone. The presence of devitalized bone sets up a vicious circle in the wound by encouraging infection which in turn causes further necrosis of bone. Penicillin jelly has proved itself to be effective in breaking up the vicious circle by eliminating or minimizing infection even in the presence of necrosed bone, and by inhibiting the soft tissue and bone infection after the sequestra are removed.

5. Skin grafting, secondary wound closure and healing by organization of blood clot have been successful in most instances in the patients in this series treated with penicillin jelly. From the author's experience and the experience of others, such procedures would seem to have been less successful without its use.

6. Topical penicillin therapy is to be considered as a part of a general plan of treatment. Good surgical judgment, proper surgical technique, maintenance of an optimum circulation in the injured part and maintenance of a proper state of nutrition are absolute essentials in the treatment.

IS THE BIOPSY OF NEOPLASMS DANGEROUS?

An Experimental Study

MARK E. MAUN M.D., and W F DUNNING Ph.D., Detroit, Michigan

CLINICIANS are prone to avoid the incision or removal of neoplasms for fear that the diagnostic procedures may serve to disseminate tumor cells but the reluctance to obtain a biopsy specimen for histologic study often delays adequate therapy and invalidates an accurate diagnosis. It is generally accepted as a truth—and there is some experimental evidence to support the belief—that the rupture of the capsule of a tumor or the destruction of adjacent tissue structures incurred in obtaining a biopsy specimen may serve to open vascular and lymphatic channels to tumor cells. Physicians therefore avoid manipulation of suspected tumors in order to prevent local extension or metastases. These concepts imply that the extent of neoplasms can be roughly judged by gross inspection and that tumor metastases are usually limited by the observed tissue barriers.

Clinical evidence supports the theory that any degree of trauma either accidental or surgically intended may serve to disseminate a malignant tumor and in rare instances to alter the nature of a benign growth. Thus students are cautioned by their elders not to squeeze or unnecessarily disturb a tumor in deed at times only a single student of an eager class is favored with an opportunity to touch gingerly the restrained new growth. Thus medical novitiates learn to regard any new lump fearfully as though its mysterious walls might disintegrate if the tumor cells were disturbed. Thus acquired fear of tumor dissemination is readily increased as the physician may unjustly attribute rapid and abundant embolic phenomena to his operative intervention in a seemingly localized new growth.

If one should accept the aforementioned theses that a tumor growth is completely localized

by its capsule, by adjacent tissue barriers or by unyielding vascular channels then interruption of such defenses might lead to a sudden catastrophe with rapid invasion of local and distant parts. However a critical study of surgical and postmortem specimens gives ample evidence that neoplasms are not restrained or unduly inhibited by their capsules or areas of marked desmoplasia since metastases may precede capsule formation and emboli may readily flow in lymphatic channels found in encircling tissue barriers. There is also adequate evidence to suggest that tumor emboli may occur throughout the life of a tumor and that growth in distal parts depends on the adaptability of the invaded tissues to the repeated attacks of viable emboli. It would not be unreasonable therefore to think that inoculation of an organ with a large mass of tumor cells might well produce a viable metastatic focus while an embolus of only a few cells might succumb to tissue defenses. Hence a decrease in the bulk of a neoplasm available for metastases should serve to decrease the incidence of metastatic tumor growth. The most likely danger therefore from cutting into a tumor would be the mechanical transfer of neoplastic cells to the operative incision. This accident seldom follows careful operative procedures.

If one examines the medical literature relative to the danger of biopsy procedures it is obvious that the experimental evidence is contradictory and inconclusive. It is therefore not surprising that clinicians are in a quandary when confronted by a suspected malignancy. The value and the dangers of biopsy were stressed in the medical literature in 1917 (3) when it was proposed to submit biopsy specimens to the Health Department of New York City. In the heat of the controversy editorialists and numerous articles written by clinicians vigorously condemned the practice of obtaining such specimens. Well known surgeons of

From the Department of Pathology, Wayne University College of Medicine, in co-operation with the Detroit Institute of Cancer Research.

that day referred to a biopsy as a criminal act, since 'incision into a breast tumor renders the prognosis grave or hopeless. The late Dr Ewing however was of the opinion that a clean surgical incision produced no untoward results and pointed out that the diagnosis was often impossible without histologic study. Tyzzer in 1913 demonstrated that daily massage increased the number of metastases in experimentally produced tumors in animals. F C Wood in 1919 injected rats with small pieces of a carcinoma and after several weeks excised parts of the tumor in one group and the entire tumor in a second group. Animals of a third group were used as controls. The animals were sacrificed in 3 to 4 weeks. The percentage of metastases in the third group that in which biopsy specimens were not obtained was 32 while in the first group the percentage of metastases was 22. In the group in which the tumors were completely excised the percentage was 21.8. In 1922 Knox in the same laboratory inoculated mice with a transplantable tumor and massaged the resulting growths daily. These inoculated animals and the animals of a control group were sacrificed 4 weeks following inoculation. It was apparent from this experiment that massage promoted metastases. Marsh working with spontaneous tumors in mice found that massaging these breast tumors increased the percentage of pulmonary metastases.

In a carefully controlled clinical study, Peterson and Nuttall selected two groups of squamous cell carcinomas of which the size, treatment, and course could be readily observed. From one group a biopsy specimen was removed with no attempt to control the degree of trauma. In the control group diagnosis was made upon clinical inspection. Both groups of tumors were treated in a similar manner and followed for a period of 2 years. At the end of this period the 166 cases in the two groups were reviewed and it was found that the incidence of metastases had not been increased by the biopsy procedure.

After reviewing the available experimental evidence Peyton was of the belief that the harmful effects of trauma had not been completely proved. He had the clinical impression that infiltration of a tumor with local anes-

thesia could disseminate a neoplasm. He injected mice with various tumors. In one group the tumors were subsequently removed under general anesthesia while in another group local anesthesia was applied about the tumor. In the latter group in which metastases were usually infrequent, pulmonary nodules were abundant following the injection of the local anesthesia. He concluded that the use of local anesthesia for the removal of a neoplasm might be a dangerous procedure.

Since present medical opinion and experimental evidence are not entirely in accord it seemed desirable to investigate the problem further employing more biologically uniform material. With the development of relatively homogenous inbred stocks of rats and mice and a diversity of carcinogenic agents, the experimenter has at his command a limitless array of transplantable tumors with 100 per cent predictability of progressive growth. By the transplantation of small fragments from an induced or spontaneous tumor into any organ or tissue of other hosts of like genetic constitution the experimenter may duplicate many thousands of times, if desired, the growth of the same neoplasm. The difference between these transplanted tumors and the same tumor in the primary host is that the causative agent is not operative in the secondary hosts. However such material is ideally adapted to the study of the effects of any procedure on tumor growth.

MATERIAL AND METHODS

The transplanted tumors used in the present experiment arose spontaneously or were induced in relatively homogenous inbred rats and were transplanted into hosts of the same inbred line. All were progressively growing neoplasms which had been propagated by transplantation from 6 to 150 generations previously.

For the first experiment IRS 4337 a very malignant Cysticercus-induced fibrosarcoma was selected. The history on transplantation of this tumor has been previously described by Dunning, Curtis, and Bullock (1). The rats were inoculated on the right forefoot with 2 milligram grafts of a tumor from the 150th transplanted generation. Nine days after in-

oculation when the tumors averaged about 0.5 centimeter in diameter they were completely excised. No attempt was made to remove a margin of healthy uninvolved tissue. The skin was secured with one or two interrupted sutures.

The tumor used in the second experiment was R 2426 a spontaneous papillary cystadenocarcinoma of the mammary gland. A study of the growth of this tumor on transplants weighing approximately 3 milligrams of a tumor from the 31st generation were inserted under the skin of the right side by means of a trocar. This tumor grows relatively slowly and the biopsy was not performed until 60 days after inoculation when the tumors weighed approximately 5 grams. An incision about 1 centimeter in length was made with a knife through the skin and a wedge shaped slice of tissue about 0.2 centimeter at the margin was removed. Since the tumors were somewhat cystic and hemorrhagic a considerable amount of bloody fluid and tissue exuded through the incision when the capsule was cut. When the hemorrhage subsided the wound was cleansed and closed with a suture.

Rats bearing transplanted adenocarcinoma of the 10th generation of R2572 were used for the third experiment. The primary tumor was a mixed tumor of the mammary gland. The separation of the epithelial portion has re-

cently been described by the authors (2). The tumors were implanted similarly to R2426 and 22 days after transplantation when they weighed approximately 5 grams a simple biopsy was performed. This tumor is fairly firm in consistence and only a small mass of tissue was removed and the wound closed with a suture.

For the fourth experiment rats bearing transplanted squamous cell carcinoma M-C 951 were used. The primary tumor was

induced by a 3 milligram pellet of methylcholanthrene in the prostate gland of an agouti Irish male rat of the 24th BxS generation of Ax-C line 9935 and has not been previously reported. Transplanted tumors of the 7th generation were used for this experiment and the biopsies were performed 20 days after implantation when the tumors weighed approximately 5 grams as in the two previous experiments.

Following the biopsy the tumors were allowed to grow until death of the rat occurred. A careful postmortem examination of the biopsied and control series included measurement and weight of the neoplasm and examination of the superficial lymph nodes, lungs and skeleton for metastases. The lungs were injected with 10 per cent formalin and preserved with a section of the tumor and the lymph nodes for microscopic examination.

All preserved tissues were examined thoroughly. The biopsied series were compared with the control series for the average number of days which they survived after transplantation and for the percentage with metastases.

RESULTS

The results are summarized in Table I. In the first experiment 19 rats of the control series bearing fibrosarcomas survived an average of 28 days after inoculation. The tumor removed postmortem weighed an average of 21 grams 15 or 79 per cent, of the rats had lymph node metastases and 17 or 90 per cent, were found to have lung metastases. In the experimental series the 19 rats which had their tumors excised 9 days after inoculation survived an average of 43 days. The difference in average survival period of 14 ± 3.8 days is statistically significant and represents the equivalent of nearly a year and a half in a man's life. The average weight of the tumors was 34 grams and larger than the tumors of the control series but the percentage of lung and lymph node metastases was not increased being respectively 84 and 63 per cent.

In the second experiment 19 rats of the control series bearing adenocarcinoma $\frac{R\ 2426}{37\ A}$

survived an average of 98 days. The tumors weighed an average of 24 grams and only 5 or 26 per cent, had lung metastases. One, or 5 per cent, had axillary lymph node metastases. The 20 rats in the experimental series survived an average of 125 days. The average tumor weight was 15 grams. Three or 15 per cent, had axillary lymph node metastases and 12 or 60 per cent, had lung metastases. The difference in average survival period of 27 ± 8.5 days in favor of the rats operated upon is also statistically significant and represents the equivalent of nearly 3 years in a man's life. The tumors were smaller than in the control series averaging only 15 grams. The difference in average weight of the tumors in this series was probably due to more extensive ulceration and the prolongation of average survival time was a result of the removal of a considerable mass of the tumor in the operative procedure. The significant increase in

percentage of lung metastases was a result of the increased survival period. Figure 1 shows the length of survival of each rat in the two series, with the individuals which showed microscopic and gross lung metastases designated by cross-hatched and blackened bars respectively. In the control series 3 rats in which lung metastases were discovered by microscopic examination survived 80, 96 and 100 days. Three rats in which no lung involvement was detected survived 101, 108 and 117 days and the 2 rats with extensive gross metastases survived for 164 and 165 days. Among the rats operated upon microscopic lung metastases were observed in 3 rats which survived respectively 89, 89 and 95 days. Three rats died after 106, 110 and 247 days respectively with no lung involvement and all but 2 which died after 106 and 117 days, respectively of those with gross lung metastases survived any of the control series which died without lung involvement.

In the third experiment 20 rats of the control series bearing $\frac{R\ 2572}{10\ A}$ survived an average

of 110 days after transplantation. The tumors weighed an average of 61 grams and only 3 or 20 per cent, had lung involvement. In the experimental series 18 rats with biopsied tumors survived an average of 113 days with tumors which averaged 39 grams and 4 or 22 per cent, had lung involvement. There were 2 additional rats in this series in which the tumors practically ulcerated out following the operation. These two hosts survived for 276 and 373 days respectively. Both had large tumors at necropsy. One had lung and lymph node involvement and the record on the other was lost. In this experiment employing a tumor of firm consistence in which the biopsy specimen comprised only a small fraction of the mass of the growth, no prolongation of survival period was noted and no difference in the percentage of metastases was detected except in the 2 instances noted in which secondary infection following the operation inhibited the growth of the tumor.

In the fourth experiment 34 rats of the control series bearing $\frac{M-C\ 951}{7\ A}$ survived an

Fig 1 The survival period and incidence of lung metastases of operated upon and unoperated upon rats bearing transplanted adenocarcinoma. R 3495 32 A

average of 93 days and the 20 rats of the experimental series in which the tumors were biopsied 20 days after inoculation survived an average of 95 days. Since these tumors characteristically ulcerate early the tumor weight in both series was based on the combined weight of the superficial lymph node metastases. In the control series the lymph node metastases averaged 15 grams compared with 13 grams in the experimental series. In the control series 31 or 91 per cent, had lung metastases while 18 or 90 per cent, of the experimental series had lung involvement. Skeletal metastases were observed in 74 per cent

of the control series and in 75 per cent of the experimental series. In this experiment like the preceding one in which the biopsy specimen was not a factor in the mass of the growth no difference was detected in survival time or percentage in which lymph node lung or skeletal metastases were observed.

COMMENTS

The concept held by many clinicians that a biopsy may enhance the growth of a neoplasm has long needed further investigation. It is generally recognized that it is often impossible by inspection alone to distinguish benign from

malignant tumors hence it is usually necessary to obtain a biopsy specimen. If physicians were to avoid incising suspicious lesions to obtain a biopsy then the early diagnosis of cancer would obviously be impossible. Unfortunately it is difficult to evaluate the effect of trauma on malignant tumors of man since the heterogeneous hereditary patterns of the hosts differ and the observed tumors seldom are identical in either their gross or their microscopic features.

In the observations recorded here in which homogeneous strains of inbred rats were in oculated with equal portions of the same transplanted tumors one could ascertain the effect of surgical trauma on the neoplasms. It is noteworthy from examination of Table I that if one removes a portion of a tumor he increases the length of life of the animal this increased survival is due presumably to the decrease in the quantity of cells available for growth. Such data confirm the recent clinical observations (10) that the surgical removal of all available tumor tissue in a seemingly hopeless case serves to prolong the individual's life for several years. Further no untoward effects are recorded by cutting into the tumor mass or by severing lymphatic channels. A survey of these reports and a study of the data reported here would suggest that the treatment of a neoplasm is facilitated by the removal or destruction of any quantity of the growth and that the hosts' survival is, thereby, proportionately prolonged.

SUMMARY

1 Rats bearing transplanted fibrosarcomas, adenocarcinoma, and squamous cell cancer were operated upon and compared with an un-

operated upon control series for length of survival after transplantation and percentage in which metastases were detected.

2 The average survival period of rats bearing transplanted fibrosarcomas was significantly prolonged by excision of the tumor 9 days after transplantation but the percentage of lung and lymph node metastases was not altered.

3 The average survival period of rats bearing transplanted adenocarcinoma was significantly prolonged by the removal of a considerable mass of the tumor 60 days after inoculation. The rats operated upon which survived the rats of the control series had a significantly higher percentage of lung metastases.

4. A simple biopsy performed on rats bearing transplanted adenocarcinoma did not affect the average survival period of the rats or increase the percentage with lymph node and lung metastases.

5 A simple biopsy of transplanted squamous cell cancer did not affect the average survival period of the rats or increase the percentage of metastasis to the lymph nodes, lungs, and skeletons.

CHRONIC OSTEOMYELITIS COMPLICATING WAR COMPOUND FRACTURES

An Evaluation of 125 Patients Treated by Early Secondary Closure

THOMAS HORWITZ, M.D., F.A.C.S., Colonel M.C. A.U.S. Ventnor New Jersey and
RICHARD G. LAMBERT, Captain, M.C. A.U.S., Hines, Illinois

THE remarkable success observed following delayed primary closure of war wounds on or after the fourth day following initial débridement and of late secondary closure following excision, either by direct suture or closure with skin flaps or grafts (Churchill) stimulated our efforts toward early closure of wounds in the treatment of chronic osteomyelitis complicating war compound fractures. We adopted a plan of conservative osteotomy followed by wound closure on the fifth postoperative day in cases in which such closure was mechanically possible and appeared warranted and penicillin was used both systemically and locally.

Observations, herein recorded and initiated September 15, 1944 have been directed toward answering the following questions:

1. What is the value of penicillin systemically and locally, in war osteomyelitis?
2. What is the optimum time for osteotomy?
3. What shall be the extent of the osteotomy?
4. What is the value of early secondary wound closure not only in diminishing the immediate convalescent period with a minimum amount of scarring and deformity but in preparing the field more adequately and more quickly for definitive reconstructive work, when such surgery will be necessary?

On our service we have accepted a minimum waiting period, following cessation of all drainage, of 3 months prior to definitive soft tissue reconstructive surgery and of 6 months prior to reconstructive bone surgery and we are convinced, following our own experience and that of others that shorter periods invite an

increased incidence of recurrent infection. Despite our anxiety to reduce this time factor we do not accept the method of widespread extirpation of soft tissue and bone recently advocated in the treatment of war osteomyelitis, as the drive to eliminate infection surgically appears greatly to exaggerate the already existing soft tissue and osseous reconstructive problems (Kelley Rosati and Murray).

TECHNIQUE

Soft tissue is not sacrificed indiscriminately. The sinus tract and necrotic skin margins are excised and the osteotomy is limited to the removal of bone that is obviously dead and detached. Any bone that appears viable is spared. Sharp edges and prominences are not removed except when they might interfere with wound closure.

The skin is undermined freely. In some cases this procedure has been carried to fully one-half of the circumference of the extremity. However, there has been no spread of infection by such extensive dissection. It often permits complete skin closure or at least a considerable diminution in the size of the wound gap. Mattress sutures of silkworm gut or wire are used in conjunction with buttons to prevent cutting in of the skin. The upper and lower portions of the wound are closed and the central portion is left open; one or two sutures being placed in readiness for closure on the fifth postoperative day.

A vaseline gauze or rubber drain is inserted into the depths of the central portion of the wound and plaster of Paris fixation is applied. Usually the posterior one-half of the previous cast is utilized and completed with a few circular bandages. On the fifth postoperative day the drain is removed through a fenestrum and the sutures are closed if the appearance of

§Both os calcis drained 10 2 months after reoperation

The wound warrants it These sutures are removed on the tenth postoperative day and the cast is closed for 1 month. Subsequent external fixation will depend on the appearance of the wound and the progress of bony union.

Femur cases are returned to balanced suspension with skeletal or skin traction depending on the state of bony union.

In cases in which complete skin closure has not been possible or advisable, healing of the residual skin defect has been materially hastened by the early application to receptive surfaces of either split skin grafts or large pinch grafts.

There have been some cases with extensive loss of soft tissue in which this method of delayed skin approximation has not been applicable. Here the extensive surfaces have been covered, even in the presence of considerable drainage, with intermediate skin or pinch grafts. In some of these cases, in which the defect has existed over bony prominences or easily traumatized areas or in the preparation of the field for definitive reconstructive measures, more adequate skin coverage has been

found necessary following this temporary skin dressing.

Dose of penicillin Systemic. Penicillin has been employed intramuscularly in 15,000 to 30,000 unit doses every 3 hours beginning at 6:00 p.m. on the evening prior to surgery and has been continued postoperatively for a minimum of 10 days. Total dosage has varied from 1,200,000 units, in mild and moderately severe cases, to 2,400,000 units in the severe cases of osteomyelitis. More recently a uniform dosage of 40,000 units every 4 hours has been adopted (Keefer *et al*). Our patients have invariably preferred periodic intramuscular injections to continuous administration by vein or muscle. The antibacterial agent was discontinued in 6 patients because of severe skin reactions, without mishap and there were 3 instances in which a clinical picture of nonspecific reaction was manifest toward or shortly following the completion of the course of penicillin—reactions attributed to impurities in the commercial preparations.

Local. Penicillin instilled in 20 cubic centimeter doses 3 times daily (250 units per c.c. of sterile water) was employed in the first group of 75 cases, a $\frac{3}{4}$ inch rubber tube having been introduced through a stab incision into the depths of the wound. This treatment was eliminated in the second group of 50 cases for purposes of comparison.

EVALUATION OF CLINICAL MATERIAL

Series A consists of 75 cases of chronic osteomyelitis treated by osteotomy and delayed closure and the use of penicillin, both systemically and locally between September 15 1944 and March 1 1945 and evaluated up to September 15 1945 (Table I).

Of this group in 73 patients (97.2%) the wounds are completely healed while in only 2 cases (2.8%) are they still draining. It will be observed that in 41 cases (54.7%) healing was complete within 2 months and that wound healing occurred in another 31 cases following drainage periods up to 9 months a total of 73 healed without reoperation. One patient with involvement of the os calcis was reoperated upon following a 10 month postoperative drainage period. Several well localized sequestra were removed the cavity walls col-

lapsed, and the wound healed 10 days later. Of the 2 patients with persistent drainage following initial osteotomy one with a localized osteomyelitis of the femoral neck has been reoperated upon 7 5 months later while the other with extensive infection in upper end of tibia and knee joint draining 8 months after operation may require a second osteotomy.¹

Cases of osteomyelitis at the ends of long bones with adjacent joint involvement have proved to be very recalcitrant. In one patient with chronic infection at the distal end of femur and involvement of the knee joint healing occurred after 8 months of postoperative drainage. In another with involvement of distal end of tibia and ankle joint healing was complete 9 months postoperatively.

Series B consists of 50 patients treated in like manner but without local penicillin. Ten patients were operated on between September 15 1944 and October 15 1944 and the remaining 40 between April 14 1945 and July 6 1945, all have been evaluated up to September 15 1945 (Table II). In this series B, wounds are completely healed in 46 (92%) patients, and in only 4 (8%) are they still draining. It

TABLE III—ANALYSIS OF 73 PATIENTS WITH HEALED SOFT TISSUE WOUNDS (SERIES A)

Time required for wound healing after osteotomy	No. patients	Average period of preoperative drainage months	Union	Large defect	No. amputations

9 months	1	4	1	1	
11 months	1	4	1		

will be noted that in 45 cases (90%) healing was complete within 2 months after operation.

No significant information has been obtained in an evaluation of the theaters of operations from which our patients have been derived. This observation also applies to the bacterial growths obtained from the wounds which revealed several types of penicillin sensitive staphylococci and/or streptococci, with a variety of other organisms which were often insensitive to penicillin. The latter groups did not appear to inhibit wound healing materially, although contributing to the amount and odor of drainage, and they tended to disappear as healing progressed.

EVALUATION OF STUDY

1. *Value of penicillin.* A comparison of the progress of wound healing in those patients treated early in Series A in whom penicillin was first employed very cautiously and in total doses from 250 000 to 750 000 units, with those treated later with more adequate total doses (1 200 000 to 2 400 000 units) has convinced us that penicillin, systemically administered is of definite benefit in the treatment of this type of chronic osteomyelitis. Although our operative technique has not varied in these cases there are other variable factors present which make the evaluation of penicillin a purely relative one and not accurately measurable viz. the duration of pre-

¹ Both cases ceased draining in 3 months following reoperation. In other words, healing has occurred in all 28 cases, or 96 per cent.

Fig. Analysis of 75 cases of chronic osteomyelitis with healed soft tissue wounds (series A). a, Relation between preoperative and postoperative drainage periods. b, Relation between postoperative drainage period and large bone defects and/or nonunion.

operative delay the severity and extent of the fracture and of the complicating infection and the anatomic site of the infectious process.

It is believed from a comparison of Series A and B that the local use of this agent has not served materially to alter the progress of

wound healing and for this reason its local use has been discontinued. Thus the nursing problem required by repeated local instillations is eliminated.

2. *Optimum time for osteotomy.* The value of adequate preoperative delay. Our patients have

often required whole blood for secondary anemia and a diet high in protein and vitamin C. Extensive drainage has been materially lessened during this waiting period by a preliminary course of penicillin. Elevation of the affected extremity has diminished edema and simple exposure of the wound has served to improve the condition of the soft tissues which are often macerated and inflamed from prolonged exposure to drainage. Adequate preoperative delay which has been tolerated well in all instances, not only encourages improvement in the patient's general condition but insures more accurate delimitation of the infection and permits progress of bony union.

A study of the figures in Table III and of the graphs in Chart 1 demonstrates a striking relationship between the duration of the preoperative and the postoperative drainage periods and the incidence of large bone defects and/or disturbances of bony union.

In an analysis of the 73 healed cases in Series A, most rapid postoperative wound healing (10 days) occurred in those with the longest preoperative delay (average 6.5 months). This must, therefore, be interpreted as the optimum waiting period in this series. It will be observed that *as the period of delay prior to osteotomy has lessened the period of postoperative drainage has lengthened and the incidence of bone defects and of nonunion has mounted*. In other words adequate preoperative delay encourages a shortening of the postoperative drainage period which means lessened soft tissue scarring. It also ensures more accurate delimitation of the bone infection which in turn permits easier definition and less sacrifice of bone by the surgeon at the time of osteotomy, less residual bone defects and a greater likelihood for firmer bony union.

It may be argued that, for example, a preoperative waiting period of 2 months with postoperative drainage for 4 months represents no greater loss than a 4 month waiting period with only 2 months of postoperative drainage. This is far from true for the case with the shorter postoperative period of drainage will show healing of soft tissues with less scarring, will probably have had less bone sacrifice at the time of sequestrectomy and bony union will be more secure.

3. Extent of osteotomy. Conservative bone excision. Only bone that is obviously dead and detached is sacrificed. Prominences and irregularities are not removed except when they may interfere with wound closure. Protruding bone is excised to the level of the surrounding granulation tissue. Bone thus spared may aid materially in diminishing the problems of bone defects and of delayed union. The wisdom of this attitude is exemplified in an early group of patients in Series A in whom all apparently infected bone was resected boldly, with resultant bony gaps, shortening and deformity, and with prolonged drainage notwithstanding and who have been faced with extensive programs of reconstructive surgery. We dislike the term 'saucerization' in the surgery of these cases for the creation of a saucer like topography of necessity implies the sacrifice of adjacent normal bone and the exaggeration of pre-existing defects.

We have observed that extreme conservatism must be exercised particularly in the excision of bone in certain regions, as for example in the lower end of the femur, the upper end of the tibia and in the os calcis. Indiscriminate resection because of the lack of adequate bone reformation in these particular areas serves to create considerable reconstructive problems, prolongs convalescence and delays functional restoration. We have observed a number of these cases given sufficient time, fill in spontaneously with scar, while the residual column of bone has been sufficiently sturdy to assume adequate functional responsibility. Thus far only 2 patients with upper tibial defects will require plastic reconstructive measures of any magnitude. Collapse of the walls and elimination of the cavity appear worthwhile in selected instances of chronic osteomyelitis of the os calcis.

A few areas of which the ilium and fibula are examples, lend themselves very well to a liberal extirpation of involved bone since this sacrifice leads to no disability whatever yet often ensures successful delayed closure.

4. Value of delayed wound closure. The extensive undermining of skin performed to permit a complete or partial closure following osteotomy has not resulted in the spread of infection in any instance. This procedure

offers a rapid method of closure with adequate skin, lessens the need for skin plastic measures, ensures less scarring and a more satisfactory bed for reconstructive surgery of underlying muscle tendon nerve and bone.

CONCLUSIONS

1 Penicillin, administered systemically in adequate doses, is of value in the treatment of chronic osteomyelitis complicating war compound fractures. Its local use has not assisted materially in wound healing and has been discontinued.

2 The purpose of early skin closure following osteotomy in the treatment of war osteomyelitis is to encourage healing of these wounds with the least amount of scarring and deformity. This result is obtained most ideally when the skin flaps may be coaptated directly as herein described.

3 Adequate preoperative delay ensures a more accurate delimitation of the infectious process. This serves to lessen the amount of bone that need be sacrificed at the time of osteotomy and allows for progression of union at the fracture site for if this is secured

the treatment of the osteomyelitis becomes considerably simplified.

4 These factors—the healing of soft tissues with the least scarring and deformity, the sacrifice of the least amount of bone and the occurrence of union at the fracture site—all serve to lessen some of the more complicated problems in the reconstructive surgery of extremity war wounds.

It is our firm belief and our statistics bear this out that the conservative approach herein described assures greater likelihood for the satisfactory control of war osteomyelitis with the least sacrifice of soft tissue and bone. Other methods in use elsewhere where the drive to eliminate infection carries with it the wide spread extirpation of soft tissue and bone, serve to exaggerate and complicate the reconstructive problems already present in these cases.

PERSISTENCE OF THE VITELLINE (OMPHALOMESENTERIC) ARTERY AS A CLINICAL PROBLEM

H. G. SMITHY M.D., and J. ALLEN CHAMBERLIN M.D. Charleston South Carolina

DEVELOPMENTAL anomalies originating in the embryonic vitelline or omphalomesenteric structures are predominantly those associated with Meckel's diverticulum. Much less common than persistent elements of the vitelline ductal system are anomalies arising from the vitelline vascular system. Despite their rarity, persistent omphalomesenteric vascular remains were recognized and described in the latter part of the eighteenth century. That they may be of singular importance as a clinical problem is attested by the ensuing discussion.

EMBRYOLOGY

Review of the embryologic development and consequently of persistent anomalies of the vitelline (omphalomesenteric) circulation begins with consideration of the yolk sac. In the human embryo the yolk sac sometimes called the umbilical vesicle is demonstrable in the earliest known specimens i.e. at the end of the second week (11). Its nutritive function is probably of minor significance but its endodermal lining gives rise to the mucosal epithelium of the major part of the digestive tract while the mesodermal layer of its wall is the site of early development of blood cells and vascular channels (1, 3). Primitive blood islands of the vascular anlage have been demonstrated in the mesodermal layer of the yolk sac wall of the Peters and von Spee embryos (13½ to 18 days of age, 12). As the yolk sac enlarges and as the primitive gut develops the two structures become connected to one another by the so called yolk stalk, or vitelline (omphalomesenteric) duct, which elongates as the embryonic body increases in size. Subsequently the yolk sac atrophies and the vitelline duct becomes incorporated into the umbilical cord. It detaches itself from the gut during the sixth week of intrauterine life. Normally the duct degenerates after its detachment. However persistence of its intra-abdominal portion occurs in 2 to 3 per cent of cases, manifesting itself definitively as the familiar Meckel's diverticulum of the ileum.

Like the vitelline duct, existence of the vitelline circulation is transient. At the fifth week of in-

trauterine life the omphalomesenteric artery is the most prominent ventral branch of the aorta. It arises from the latter by several roots and passing ventrally toward the umbilical cord divides to surround the primitive gut by an arterial ring at the point of junction of the gut with the omphalomesenteric duct (Fig. 1). In its subsequent course, it is paired so that two vitelline arteries are identifiable in the early embryo (5 weeks). The paired vessels leave the embryo accompanied by the vitelline duct and are distributed as a ramifying plexus over the surface of the yolk sac. Coincidentally with atrophy and degeneration of the yolk sac, one of the paired vitelline arteries disappears. The remaining one develops further and comes to lie in the mesentery of the midgut, supplying the latter with blood and becoming definitively the superior mesenteric artery (Fig. 2). According to Cullen its connection with the umbilical cord may persist long after the vitelline duct has disappeared, which normally occurs at approximately the sixth week of intrauterine life. Whatever may be the temporal relationship the vitelline artery normally loses its umbilical attachments to remain as the superior mesenteric artery.

The vitelline veins arising in the wall of the yolk sac, are paired. The two vessels enter the abdominal cavity of the embryo at the umbilicus accompanied by the vitelline artery and duct. From the umbilicus the two venous trunks course cephalad, following the path of the gut to empty into the primitive heart. At the fifth week of embryonic development, the liver bud begins to expand and interrupts the vitelline veins in their course toward the heart. One of the vessels becomes incorporated for the most part in the growing hepatic sinusoidal system while the other atrophies and disappears. The surviving vessel receives the superior mesenteric vein and the splenic vein just before entering the liver and becomes finally the portal vein.

CLINICAL SIGNIFICANCE

Persistence of the omphalomesenteric artery manifests itself anatomically as an adventitious intra-abdominal cord covered by peritoneum. Usually it is attached firmly at its two extremities

Fig. 1. Origin of paired omphalomesenteric arteries from primitive aorta in the early embryo (5 weeks). Note relationship to junction of the omphalomesenteric duct and intestine.

one to the anterior abdominal wall at the umbilicus and the other to the mesentery of the terminal ileum. By such an arrangement there is formed a tense band traversing the abdominal cavity in an anteroposterior direction. Its potential danger as a source of intestinal obstruction is obvious. Persistent vitelline arterial remnants may be associated with a Meckel's diverticulum, in which

instance a free band is formed connecting the diverticular mesentery to the umbilicus or to the ileal mesentery. The resulting anatomic arrangement is a ring or loop through which coils of intestine may pass to become strangulated. The least common form of persistent vitelline artery is that situation in which the vascular remnant is attached only at its mesenteric end, the remainder of the vessel hanging free in the abdominal cavity.

Clinically it is significant that only 4 cases of persistent omphalomesenteric artery producing no symptoms have been reported. Of these only one was an adult, a dissecting room cadaver studied by Derbes and Hoge, showing both persistent artery and Meckel's diverticulum; the case record contained no mention of abdominal discomfort during life. The others were infants examined at autopsy, 2 of whom the anomalous vessels were unattached at one end hanging harmlessly free in the abdomen (Meckel and Ruge) while the third was a newborn child found to have both mesenteric and umbilical attachments intact (Geail). Inasmuch as 3 of the asymptomatic patients were infants it is striking that the literature provides only one adult patient showing no clinical disturbance as a result of persistence of the vitelline artery.

Table I contains a summary of the literature of 12 cases of persistent vitelline artery in which disturbing clinical symptoms were present. Nine of the cases terminated fatally, a mortality rate of 75 per cent. All but one of the deaths were due to acute intestinal obstruction. The remaining fa-

examination were confirmatory of a diagnosis of acute intestinal obstruction. Exploration of the abdomen revealed a stout cord attached at the umbilicus and passing posteriorly to disappear in the retroperitoneal tissues just below the third part of the duodenum. In its course, the cord had encircled a segment of intestine causing complete obstruction of the closed-loop type. The patient died on the fifth postoperative day. Histologic studies confirmed the presence of venous elements in the adventitious band.

CASE REPORT

Roper Hospital No. 39778. A Negro laborer 35 years of age was admitted to the hospital June 30, 1945, complaining of abdominal pain of 6 months duration. He stated that his pain was intermittent in character, located in and around the umbilicus and in the epigastric midline between the xiphoid and the navel. The pain was exacerbated by erect, standing, walking, straining, coughing, and remaining relieved by reclining. For this reason, the discomfort was noticed rarely at night. Near the end of a day's work, the patient revealed that the pain was at its worst and that vomiting occasionally occurred under such circumstances. There was no radiation of the pain and it was not influenced by eating or hunger. There was no history of hematemesis, bloody or tarry stools, jaundice, constipation, or diarrhea. History of the other body systems was noncontributory.

Physical examination revealed the following: temperature, 98.6°; blood pressure, 124/75; pulse and respiration normal. The patient was well developed and well nourished. Abdomen was flat and moved with respiration. There was no distention, muscle spasm or rigidity and no masses were palpable. Tenderness was present on pressure upon the right upper quadrant, but was not excessive rebound pain was absent. On auscultation, peristalsis was audible and of normal character. Rectal examination was negative. Remainder of examination showed only irrelevant findings.

Laboratory studies showed white blood cell count 9,500 with normal differential count, hemoglobin, 18 grams. Urinalysis showed normal urine. Analysis of gastric contents showed normal findings. X-ray of gastrointestinal tract after ingestion of barium showed no abnormalities. Blood Wassermann and Kline tests were negative.

A specific diagnosis was not made but in view of the persistent nature of the patient's discomfort and because he was incapacitated by his illness, laparotomy was done 5 days after admission.

Under spinal anesthesia, the patient's abdomen was entered through a right paramedian incision. A firm, extremely taut fibrous cord, covered by peritoneum, was found attached at one extremity to the under surface of the umbilicus and at the other to the mesentery of the terminal ileum 3 centimeters from the ileocecal junction (Fig. 3). The band did not enter the lumen of the ileum. Dissection at the mesenteric attachment revealed the terminal portion of the cord to fan out into numerous small, fibrous, filamentous strands which lost themselves between the two leaves of the mesentery (Fig. 4). The main cord looped over the ileum to the left of the latter in such a way as to support in part the weight of the terminal ileum and cecum when the patient was erect (Fig. 3). However, there was found to be no agglutination of the ileal serosa to the covering of the adventitious band so that there was no evidence of obstruction or compression of the intestine. Furthermore, the cord

was not adherent to any other viscera along its course to the umbilicus. Traction upon the anomalous structure at its ileocecal extremity caused dimpling and inversion of the umbilicus as observed from without. Further exploration revealed no abnormalities of the abdominal viscera. There was no Meckel's diverticulum. The cord was clamped and ligated at its two extremities and excised in its entirety. After removal of the appendix, the abdomen was closed in layers.

Follow-up examinations at 4 and 10 weeks after operation have found the patient to be entirely free of pain. He has returned to work and is considered to be cured.

Pathologic examination of the removed specimen, which measured 9 centimeters in length, revealed a tough cord selected from various segments of the cord, demonstrated centrally located, thick walled, patent artery surrounded by a zone of loose fibrofatty tissue a layer of more compact subserosal areolar tissue, and an external covering of serosa (Fig. 5). Higher magnification of the central artery showed a well defined internal elastic lamina and a patent lumen containing red blood cells, some of them in rouleaux formation (Fig. 6).

The occurrence of abdominal pain in this patient was apparently on a mechanical basis. Review of Figures 3 and 4 explains the traction type of discomfort which was noticed only when the individual was standing erect. In this position the gravity effect was such that the full weight of the cecum and, most probably several loops of small intestine, in addition to the terminal ileum, was exerted upon the adventitious band. This in turn produced traction upon the peritoneal surface of the umbilicus. In the recumbent position tension of the cord was reduced materially and the umbilical traction eliminated. Vomiting, which was said to occur at the peak of intensity of the pain, was more likely of the reflex origin, due to traction upon the periumbilical parietal peritoneum, than to actual obstruction of the bowel.

Of interest is the fact that no symptoms referable to the abdomen occurred until the patient was 35 years old. While difficult to explain, it is significant that the patients reported by Mahomed and by Buchanan and Wapshaw developed their first symptoms after 18 and 12 years respectively. Postoloff's case was 36 years old before noticing abdominal discomfort. On the contrary Shaw's patient, who was 43 years of age, had suffered from lower abdominal pain since childhood.

Intestinal obstruction is the most common (and most serious) complication of persistent omphalo-mesenteric vessels. That no evidence of ileus was found either at operation or in the patient's history may be regarded as coincidental. In respect to the production of symptoms by vitelline vascular remains in the absence of mechanical obstruction, the case is similar to those reported by Shaw and by Gautier. It is probable that intestinal obstruction would have supervened

eventually if the adventitious band had not been removed

SUMMARY

- 1 The embryologic development of the vitelline vascular system is reviewed briefly
- 2 A review of the literature of persistent vitelline vascular elements is presented in tabulated form and their clinical significance discussed
- 3 A case of persistent vitelline artery causing disabling symptoms which were relieved by operation is reported.

A STUDY OF THE EFFECT OF PROPHYLACTIC ORAL SULFADIAZINE UPON INFECTION IN SOFT TISSUE WAR WOUNDS CLOSED SECONDARILY

STANLEY O HOERR, M.D., Major M.C., A.U.S. Boston, Massachusetts

THE well controlled statistical studies of Meloney and his associates has cast serious doubt upon the efficacy of systemic sulfonamides in preventing infection in traumatic wounds. This present study on the other hand, although dealing with a somewhat different problem, indicates that sulfadiazine, given orally at secondary closure of soft tissue war wounds, reduces the incidence of infection and is associated with better healing.

The multiplicity of factors involved in wound healing makes the critical evaluation of any one factor difficult. It is difficult to carry out controlled and impartial experiments in a laboratory; the problems are greatly increased when one deals with patients rather than guinea pigs and under war conditions it may at times appear impossible to obtain sufficiently accurate and detailed records, or observe the patient long enough to assess results. Furthermore, in the treatment of battle casualties the emphasis is upon producing the best immediate results by any and all means—a relatively innocuous drug like sulfadiazine is likely to be freely used if it promises any conceivable benefit to the patient, rather than withheld in selected cases to help determine its true value.

In the treatment of the 200 soft tissue wounds which form the basis for this study it must be admitted at the outset that the aim was to procure the best possible results in each case, and not to conduct an experiment on the prophylactic value of sulfadiazine. The situation has been further complicated by the fact that in some instances penicillin as well as sulfadiazine has been employed prophylactically (Penicillin was not available for routine use in the light injuries which constituted most of the wounds.) Nevertheless, the very fact that wounds which promised difficulty were treated with prophylactic sulfadiazine, lends weight to any differences which can be shown to favor the sulfadiazine treated group since it may be assumed that the bulk of the worst wounds will be included there.

It is perhaps worth mentioning at this point that little was expected from sulfadiazine as a prophylactic when the series was begun. In common with many other surgeons we regarded it with a skeptical eye. It was first used in those patients who had wounds which promised trouble (as in deep wounds, or wounds which closed with considerable tension) or in whom good healing was of particular importance (as in wounds with associated damage of a peripheral nerve). Stock was taken after 150 wounds had been closed and the value of the drug appeared sufficiently established to warrant its routine use.

It might seem from the difficulties detailed in the foregoing paragraphs that no valid conclusions could possibly be drawn in this report. Some advantage may derive from the fact, however, that the series is both consecutive and in every sense a personal one. The writer supervised the preparation of the wounds for closure, employed a uniform technique in operating upon them and personally observed their postoperative course. This at least eliminated the inevitable differences in judgment between individuals as to when a wound is ready to close, how it should be closed, and what constitutes a wound complication.

MATERIAL AND METHODS

Material. The series consists of 200 consecutive personally performed secondary closures upon soft tissue wounds in 131 soldiers. 40 of the wounds were in 39 German prisoners of war. 151 wounds were caused by high explosive fragments. 47 wounds were caused by bullets, and 3 by non-battle trauma. The wounds were all incurred in France and Germany between August, 1944, and April, 1945. In all but 7 wounds, preliminary debridement was carried out in forward hospitals and the patients transported to this general hospital anywhere from 1 to 25 days after the debridement. Compound fractures were excluded from the series, as were wounds in certain patients being promptly evacuated for other conditions (such as cerebral injury) which precluded a satisfactory period of observation. During this entire time it was the fixed policy of the surgical service

Read before the Society of University Surgeons, February 9, 1946, New York, N. Y.

HOERR ORAL SULFADIAZINE AND SOFT TISSUE WAR WOUNDS

to close either by suture or graft all wounds at the earliest practicable time. Recognized exceptions were wounds so small that they could be expected to heal spontaneously within 2 weeks, deep wounds with small openings, wounds presenting severe and persistent infection (not more than 2 or 3 wounds were excluded for this last reason during the entire period). In general closure was preferred to grafting whenever it could be effected.

Ninety three wounds represent a consecutive series for the entire hospital that is, every secondary closure performed in the hospital was carried out by the writer during this time, to prevent an artificial selection of easy cases for the series. (Actually all wounds which promised difficulty in closure have been consistently turned over to the writer because of his interest in the problem.) The final results in the entire series are comparable to other published series of secondary closures. Seventy-eight per cent of the wounds were solidly healed in 2 weeks or less.

Preparation of the wound. The appropriate time for closure was determined by the gross appearance of the wound. No closure was performed at the first dressing but wounds which were clean when first seen were closed after a day or two of saline or azochloramide dressings. Wounds which were dirty or infected were treated with meticulous dressings of 1:3000 aqueous solution of azochloramide once or twice daily at which time slough was picked off. Debridement was necessary followed by secondary closure a few days later. Edema or induration at the wound edges was permitted to subside. Once the wound was grossly clean secondary closure was carried out. In some wounds appreciable delay in closure and even in the start of systematic preparation took place because of the press of more urgent work.

Operative procedure. The procedure carried out depended entirely upon the physical character of the wound and fell roughly into one of three general types. In those wounds supple enough to permit it (chiefly those received within 10 days of debridement) a simple closure was performed with widely spaced deeply placed vertical mattress sutures of silk usually a heavy silk suture were not burned. Heavily scarred wounds were carried out *en bloc* and closure carried out with buried sutures of fine silk or cotton to the skin. There was an intermediate group in which there might be undermining of skin edges, or excision of exuberant granulation tissue, or modification of

TABLE I.—WOUND COMPLICATIONS
Wounds having more than one complication have been listed here only once under the most serious. Any infection has been given priority over any technical complication

the shape of the wound to facilitate closure, these have been grouped as *wound revision*. In this group buried sutures of fine silk or cotton might or might not be used. Catgut was not used in any wound. In an occasional wound with marked tension retention sutures over gauze pledgets were employed. In some of the wounds treated early in the series, sulfanilamide powder was lightly dusted into the wound this was discontinued later. There were no instances of so-called 'partial closure in this series.

Chemotherapy. The usual scheme for the employment of sulfadiazine as a prophylactic was to begin it as soon after the secondary closure as the patient could take it. 4 grams was given as an initial dose and this was followed in an hour by a 1 gram dose after which he received 1 gram every 4 hours for 6 days. The penicillin dosage was 20,000 to 30,000 units intramuscularly every 3 hours for 2 to 5 days. Nine patients with 19 wounds were given sulfadiazine before as well as after closure, 2 patients with 3 wounds received penicillin as well as sulfadiazine before and after. These are not treated as a separate group since any advantage possibly resulting from the pre-closure use of sulfadiazine is still a feature of its prophylactic value. There were only 2 instances of untoward reaction to sulfadiazine—both febrile—among the 92 patients who received the drug.

Postoperative care. In general, patients who had wounds of the lower extremity were kept in bed until healing was sound. Splints were freely employed. Sutures were removed from the sixth to tenth day depending upon the appearance and

location of the wound emphasis was placed upon supporting the suture line with adhesive strapping (which was often applied immediately after operation as well). Sulfadiazine was employed therapeutically in 7 instances, and penicillin in 4 instances after infection had appeared in a wound. Their use in these cases has not been regarded as prophylactic although they may have contributed to the swifter healing of the wound. In 1 case particularly penicillin appeared to abort a serious cellulitis.

Appraisal of complications. This feature of the study is of paramount importance. Ideally a single person, other than the surgeon, should follow all the wounds, since surgeons are some times reluctant to see blemishes in their own handiwork. Unfortunately this ideal arrangement could not be followed but the writer made an honest effort to be both strict and uniform in

applying criteria of wound healing and to note even the most minor complications. Some evidence of strict interpretations is to be found in the fact that although 78 per cent of the wounds were healed in 2 weeks or less, 55 per cent are listed as having a complication of one sort or another (Table I).

Complications were recognized as of two general types: technical and infectious. A heavy line may separate a "cutting suture" from a "mild stitch abscess," or "induration" (as seen in a wound closed under tension) from "moderate cellulitis," although average examples in each group usually are clear enough. Wounds having both infection and a technical complication have been listed only once under the heading of infection. In each group of cases the wound was listed only under the most severe complication which it presented.

The total healing time from secondary closure was determined for each wound. Here again there is latitude in interpretation but a wound was not regarded as healed until epithelialization was complete. In all but 2 or 3 instances the patient was kept under observation a sufficient length of time to determine the primary fate of the wound. In these exceptions the patients were transferred out 7 to 10 days after secondary closure, but healing seemed to be progressing normally at that time. In 5 cases it was possible to record the onset of late complication a week or more after apparent wound healing of the wound. It is necessary to point out, however, that in many cases the development of a late complication would not have come to our attention since the patient was promptly discharged to duty when thought fit and readmission would have been more than

likely at another hospital. This is an important but unavoidable limitation of the study.

ANALYSIS OF DATA

The following facts stimulated the present study. 44 wounds received no chemotherapy at the time of closure. Infection developed in 21 or 48 per cent. 107 wounds received oral sulfadiazine at the time of closure. Infection developed in 23 or 22 per cent. The difference is statistically significant (1). Rather than being a final conclusion this fact can only be the starting point of a detailed investigation since in a series of small it might well be a result of an artificial selection of wounds, or the unsuspected operation of other factors. For example the 107 wounds in which sulfadiazine was employed might have been the smallest, soonest treated and cleanest wounds of

SURGERY GYNECOLOGY AND OBSTETRICS

TABLE IV—COMPARISON OF INCIDENCE OF INFECTION AND DELAYED HEALING (15 DAYS OR MORE) IN U.S. SOLDIERS AND GERMAN PRISONERS

Effect of chemotherapy in wounds treated by excision and closure after delay of 15 days or more from original debridement.

Oral sulfadiazine & Penicillin	20	4	20	14	7	1	14	12

the entire series, and could be expected to heal well with or without sulfadiazine. In asaying the true effect of chemotherapy therefore it is necessary to account for the operation of the variables affecting wound healing and the development of infection.

Two standards of comparing groups of wounds have been utilized, in an effort to compensate for ambiguities or errors inherent in either system.

Incidence of infection. To determine the incidence of infection, each wound listed in Table I as having an infectious complication, no matter how trivial, has been tabulated. (Certain of these infections have been designated as serious, either on the basis of constitutional symptoms which they produced, their extent, or their persistence. They are briefly considered as a separate group in Table X.)

Incidence of retarded healing. Any wound not solidly healed in 14 days or less has been regarded as delayed in healing. A number of wounds with trivial infections (such as stitch abscesses) were well healed within 14 days. On the other hand, certain wounds without obvious infection were retarded (as in an unhealed drain site, or an undetected small separation of the suture line). The advantage of using this criterion as well lies in the fact that in some of these wounds been unrecognized low grade infection further more the best overall guide to therapy in these wounds is the healing time.

In an effort to circumvent the difficulties introduced by the use of both sulfadiazine and penicillin in certain wounds, the following division of the 200 wounds has been made: group A—no chemotherapy 44 wounds; group B—oral sulfadiazine only at time of secondary closure, 107

TABLE V—EFFECT OF LOCATION OF WOUND UPON INCIDENCE OF INFECTION AND DELAYED HEALING (15 DAYS OR MORE)

Location	All wounds				All wounds except in German prisoners

wounds; group C—oral sulfadiazine and intramuscular penicillin at time of secondary closure; group D—oral sulfadiazine with or without intramuscular penicillin at time of secondary closure (group B plus group C) 143

The 44 wounds in group A are the control group. They are compared throughout with the 107 wounds in group B and also the 143 wounds of group D. Some of the most difficult wounds of the series are to be found in group C, which explains why both agents were given as prophylaxis. This is reflected in the fact that there were 11 infections and 11 instances of delayed healing in these 36 wounds—a much higher incidence than is found in group B. It is therefore unfair to utilize group C as an independent group, but it is also impossible to exclude it from consideration. By running a dual comparison between groups A and B and D it is possible in group D to account for all infections which developed despite sulfadiazine, in group B on the other hand (which is roughly comparable to group A), absence of infection can be credited to the sulfadiazine alone. In group D the absence of infection would be with perfect justification partly attributable to penicillin. In practical application group A is to be compared with whichever shows the higher incidence of infection or delayed healing—groups B or D.

The 10 wounds in which penicillin was the sole prophylactic agent developed 4 infections, and 4 wounds had retarded healing—this group of wounds is used only in analyses of the series as a whole. Three wounds failed promptly and with out evidence of infection from purely technical

cases 2 from extreme tension and 1 from unobliterated dead space (not a hematoma) these three wounds have been also excluded from comparisons, since the failure was inevitable irrespective of a chemotherapeutic agent.

Tables II and III represent an analysis of the series as a whole from the standpoint of those factors thought most likely to affect the incidence of infection and delayed wound healing. The basic data are not very satisfactory in the category listed as chemotherapy at time of injury. The data were taken from the individual field records. No account is taken of the duration of the therapy or of the dosages employed. In some instances perhaps only a single dose was administered. It is possible that some patients did not receive the chemotherapy that the record stated they were given. It is probable that others were given some prophylaxis (since it was Army routine) in spite of the fact that it was not mentioned on the record. In busy forward hospitals, where the highest priority is given to the care of the seriously injured, errors in recording data

that have no great bearing on management of the lightly wounded are readily understandable. (Dates of injury and operation by way of confirmation, are very reliable.) Although there is an apparent increase in the incidence of infection in those who received no chemotherapy at the time of injury and although it is of great importance to determine its value further analysis in this paper is not warranted. It is of passing interest, however that what data there are in keeping with the conclusions of this study (This holds true for German prisoners as well as majority of whom received chemotherapy when injured.) Factors presenting significant increases in the incidence of both infection and delayed healing are the following: wounds in German prisoners yielding pathogenic bacteria when cultured at the time of closure and finally wounds in patients who did not receive oral sulfadiazine at the time of closure. Perforating wounds, delay in closure of the wound or delay in preparing it for closure, closure of the wound by block excision (usually related to delay) and failure to receive

chemotherapy at the time of the original injury all show significantly increased incidence of infection but not of delayed healing.

The apparent susceptibility of German prisoners to infection demands further investigation. Cross analyses of the principal factors affecting infection in this series with respect to each other (not shown in the paper) demonstrates that in each separate category there still exists a significantly increased incidence of infection in the group of German prisoners as compared with United States soldiers. The most natural assumption to make in connection with poor results in German prisoners, namely, that it is largely due to delay between time of debridement and closure (with resulting block excision of the wound) is refuted by Table IV which specifically

compares the prisoners with United States soldiers on these two counts combined. Whatever the reason for the increase, whether debilitation, faulty nutrition or some other unsuspected cause, it is desirable to exclude German prisoners from further analyses of the effect of prophylactic chemotherapy.

Table V is an analysis of infection and delay cross analyzed by the location of the wounds. When corrected by excluding German prisoners, it can be seen that location is not a factor of much significance in this series.

Tables VI and VII repeat the analyses of Tables II and III excluding German prisoners. Partly because there are fewer cases (and the percentage differences must be correspondingly greater to register as significant) and partly be-

cause most of the differences are actually less, the only factors which continue to show significant increases in the incidence of infection are the presence of pathogenic organisms in the wound at time of closure and the lack of prophylactic oral sulfadiazine at the time of closure. However expected trends in other factors are still discernible although not so marked. It becomes worthwhile at this point to cross analyze these influential factors separately from the standpoint of prophylactic chemotherapy at the time of closure.

In Tables VIII and IX the incidence of infection and delayed healing is considered from the standpoint of those factors appearing to favor their development as related to the use of oral sulfadiazine. Significant differences are not indicated on these tables, because the breakdown produces wound groups with relatively few wounds. It is intended to show a trend however demonstrating a lower incidence of infection and retarded healing in the sulfadiazine-treated cases in almost every category. The only groups of wounds which fail to support this trend are those wounds requiring prolonged preparation and those wounds treated either by excision or revision and closure (This is also demonstrable

in Table IV) What there is about these wounds that should cause them to fall outside the general trend is not clear. Further analyses are not enlightening, and it must simply be recorded as a fact.

Table X considers the problem of the serious infection. In none of these patients did infection threaten life but in 18 wounds the infection was definitely more than trivial. There is again seen a sharp increase in the incidence of serious infection in German prisoners and again an increased incidence in those wounds not treated with prophylactic sulfadiazine. There are insufficient cases to render the difference significant in either prisoners or United States soldiers considered separately although when they are combined there is a significant advantage for the group which received sulfadiazine.

Table XI is a breakdown of the 73 consecutive wounds which were aerobically cultured at the time of secondary closure. It is unfortunate that all the wounds in the series were not cultured since the cultured group is not quite representative of the series as a whole (there is a higher incidence of infection than in the entire series). The common pyogenic organisms are considered

TABLE IX.—EFFECT OF ORAL SULFADIAZINE ADMINISTERED AT TIME OF SECONDARY CLOSURE, CROSS-ANALYSIS BY FACTORS WHICH TEND TO FAVOR INFECTION AND DELAYED HEALING—GERMAN PRISONERS EXCLUDED

and again the analysis is subdivided according to the nationality of the patient. The numbers are so small that percentages have not been used, but the over-all trend slightly favors the wounds in which prophylactic sulfadiazine was employed. Once more this is less convincing in the group of German prisoners apparently being a German prisoner had a more decisive effect upon the healing of the wound than any other factor concerned.

Since as many as 5 wounds were closed at one sitting upon a single patient, and since the chemotherapy employed on the patient affected all 5 wounds equally, the objection might well be raised that it is unfair to treat the wounds statistically as separate from the patient. For example, 15 wounds on 3 patients not receiving sulfadiazine might all become infected and they might all have been the result of three breaks in operating room

TABLE X.—EFFECT OF ORAL SULFADIAZINE ADMINISTERED AT TIME OF SECONDARY CLOSURE UPON INCIDENCE OF SERIOUS INFECTION

	All cases			U.S. soldiers			German prisoners		
	Cases	Serious infection	Per cent	Cases	Serious infection	Per cent	Cases	Serious infection	Per cent
All wounds	187*	18	10	146	10	7	23	3	
No chemotherapy	43	10	23	33	3	10	3		43

technique. This would obviously upset the entire series in a way not shown in the previous tabulations. Table XII deals with the series as patients rather than wounds. (A discrepancy of 3 extra patients shown in this table is accounted for by the fact that in 3 cases wounds were closed at two sittings a week or more apart for the purposes of this analysis the patients were regarded as new patients at the second operation.) An infection developing in any of the patient's wounds causes that patient to be listed under "infection" similarly with delayed healing. The over-all advantage for the sulfadiazine-treated patients is once more demonstrated as a trend.

The bulk of the cases not treated with sulfadiazine were in the early part of the series. A final objection might be raised that improved results came about as a consequence of better treatment of the later wounds (when experience was greater) rather than from the use of the sulfadiazine. Of the first 75 wounds 30 received

no chemotherapy. Infection developed in 13 of the 30 and there was delayed wound healing in 11. Of the second 75 wounds, 12 received no chemotherapy and in these 12 there was infection in 8 and delayed wound healing in 5. In the last 50 wounds 2 received no chemotherapy with no infection and no delayed healing. Although the majority lie in the first 75 wounds a high incidence of infection also occurred in those wounds placed later in the series.

Numerous cross-analyses of the data have been made which are not included here. They have all followed the same general trend showing an advantage for wounds treated prophylactically with oral sulfadiazine. It is believed that all the contradictory evidence has been presented.

DISCUSSION

Attention has been drawn to weaknesses inherent in an analysis of this particular group of wounds from the standpoint of the effect of

TABLE XII.—INCIDENCE OF INFECTION AND DELAYED HEALING (15 DAYS OR MORE) IN PATIENTS EFFECT OF ORAL SULFADIAZINE ADMINISTERED AT TIME OF SECONDARY CLOSURE

	Incidence of infection								
	All patients			U.S. soldiers			German prisoners

Oral sulfadiazine + Penicillin	0	3	3	7	4	57	2	0	43

The differences are not significant statistically. Infection or delayed healing in any wound of several on the same patient, places the patient in the appropriate group, although all the other wounds might have healed perfectly. (See text for details.)

prophylactic sulfadiazine. They lie in the small size of the series, and in the fact that therapy was not originally planned as a research project. On the other hand, the series is personal, consecutive, and accurate observations on the fate of each wound are available—a set of circumstances not frequently met with where battle casualties are concerned.

A number of factors affecting wound healing and development of infection have been analyzed. German prisoners were shown to have a high incidence of infection and delayed healing in respect of other factors, and the bulk of the analysis has therefore excluded them. It has been shown that wounds which were excised and closed, or which had prolonged delay before closure did not appear to have a significant response to prophylactic chemotherapy the reasons for this are not clear. Wounds in nearly every other category appear to benefit by a course of oral sulfadiazine given prophylactically at the time of secondary closure. The general trend is rendered more significant by the fact that by and large the worst wounds received chemotherapy on empirical grounds in the interest of obtaining the best possible results. (Evidence for this statement is the high incidence of infection and delayed healing in the small group of wounds in which

both sulfadiazine and penicillin were employed prophylactically.)

Suggestive evidence that prophylactic chemotherapy at the time of the original injury—days or weeks before the patient reached a general hospital—decreases the incidence of infection after secondary closure was not pursued because of the likelihood of error in the recordings on the field record of the patients. A consideration of the value of topical sulfanilamide employed at the time of secondary closure is likewise beyond the scope of this paper.

It is recognized that the conclusion in this study is at variance with those of Meleney arrived at in an elaborate statistical study of a much larger series of cases. The two series are not strictly analogous, however. These are wounds produced by the missiles of war as opposed to wounds incurred through civilian trauma. These are wounds in which closure is delayed deliberately for days or weeks after injury as opposed to civilian wounds the vast majority of which can and should be closed as soon after the original injury as possible. Finally these are wounds in patients who have already received, for the most part, some type of prophylactic chemotherapy; perhaps this early chemotherapy inhibits the growth of certain bacteria which lie latent in the

wound until stirred up by operative closure when they will produce infection unless inhibited again by another course of chemotherapy. Perhaps this early chemotherapy renders the wound more susceptible to infection at later operation than it would have been had no prophylaxis been used at all and the wound permitted to develop unaided its own local tissue immunity.

CONCLUSION

A personal, consecutive series of 200 secondary closures of soft tissue war wounds is analyzed

from the standpoint of the prophylactic effect of sulfadiazine administered orally at the time of closure.

The evidence presented favors the view that sulfadiazine so employed is beneficial and that it reduces the incidence of postclosure infection and delayed healing.

THE PELVIC AUTONOMIC NERVES IN THE MALE

FRANKLIN L. ASHLEY M.D., and BARRY J. ANSON Ph.D (Med. Sci.) Chicago, Illinois

NUMEROUS descriptions of the pelvic plexus of nerves are to be found in the literature. Although some of them are excellent neurologically none provides serially arranged illustrations prepared from actual gross dissections. In the present article it will be the authors sole purpose to portray the structure of the pelvic plexus and associated nerves in atlas fashion, with description of related layers and organs.

LITERATURE

Anatomy According to Davis (1933 1934) the pelvic plexuses consist of interlacing groups of nerve fibers and of many but extremely small ganglia situated on either side of the ampulla of the rectum. The dimensions of each plexus are said to be 2 by 3 by 1 centimeter. The two plexuses are described as embracing the rectum in the manner in which the levator muscles embrace the anal canal. On each side the plexus is bifurcated, the medial sheet being a continuation of the hypogastric nerve, the lateral a prolongation of branches derived from the sacral nerves. The two hypogastric nerves are joined at a lower level in the pelvis by parasympathetic fibers of the second to fourth sacral segments, these fibers making up the nervus erigens. The two contributions, together with sympathetic fibers from the pelvic chain ganglia, form the pelvic plexus.

The central connections, according to Whitte (1935) are made up of preganglionic fibers from lower thoracic and upper lumbar levels of the intermediolateral columns of the spinal cord. Cells send out axons over the white rami of the lower thoracolumbar outflow to lumbar and pre-aortic ganglia. Postganglionic neurons originate in sympathetic trunks as well as in pre-aortic ganglia to form a plexus which descends with the abdominal aorta. At the level of the inferior mesenteric artery are situated two small ganglia which, supplying a circumarterial plexus for branches of the inferior mesenteric artery ultimately innervate the sigmoid colon and rectum. The remainder of the descending sympathetic fibers form the superior hypogastric plexus in the region of the bifurcation of the aorta. The plexus divides into two plexiform sets of nerves which

enter the pelvis, along its lateral wall as the hypogastric nerves (or plexuses).

Pelvic roots, forming the nervi erigentes, arise from medial aspects of the anterior primary divisions of the second to fourth sacral nerves, 1 to 1 centimeters from their foraminous exits. They course to the pelvic plexus, or directly to the rectum. Two or three fine twigs arise from each of the ganglia of the sacral sympathetic chain and enter the posterior border of the pelvic plexus.

The urinary bladder receives sympathetic fibers from the celiac, renal, and mesenteric ganglia, as well as from the first four lumbar ganglia of the sympathetic chain. These fibers, by way of the hypogastric plexuses, and in descent into the pelvis, receive fibers from the last lumbar ganglia, from the inferior mesenteric plexus, and from the superior hemorrhoidal nerve. They also receive fine filaments from the sacral sympathetic chain.

The parasympathetic fibers (from sacral roots) first gathered together as the nervi erigentes, separate into three groups the upper supplies the fundus of the bladder the middle supplies the midportion of the bladder and the lower courses to the inferior aspect, the vesical neck, and the adjacent portion of the urethra.

The cells of origin for these efferent fibers (parasympathetics) to pelvic organs lie in the intermediolateral column of the sacral region. The locations of cell bodies for the afferent fibers are as yet undetermined, but are probably in posterior root ganglia.

The prostate and seminal vesicles receive their innervation from the middle group of fibers while the rectum is innervated by the inferior group and by some fibers, which, remaining independent of the pelvic plexus, are sent directly from the hypogastric nerve and chain ganglia.

Physiology The sympathetics, according to Davis (1934) and Meigs (1940), behave as vasoconstrictors and as inhibitors of the musculature of sigmoid colon, rectum, and bladder. They cause ejaculation and contraction of the sphincter of the bladder. Pseudosensory properties are regarded as vasomotor in foundation. The fibers are also glandulomotor to both superficial and deep glands.

The parasympathetics produce vasodilatation and release of the various sphincters. They mediate pain sensation from the bladder. Section of

Contribution No. 444 from the Anatomical Laboratory of Northwestern University Medical School, Chicago, Illinois

Fig. 1. Topography of the hypogastric plexus and related pelvic structures in a hemisectioned specimen peritoneal level (successively deeper levels of same specimen in Figs. 2 to 6). The left half of a male pelvis, peritoneum intact. The section passes through the entire length of the rectum

and through the urinary bladder, urethra, etc., and prostate (latter hypertrophied). The section also passes through the interpubic fibrocartilage, seminal vesicles, retropericolic plexus of veins, scrotum, and penile cavernous tissue.

the superior hypogastric plexus does not cause atrophy, or disturbance of any motor functions of the bladder. excision of parasympathetics would cause increased blood supply to the pelvis, a lessening of visceral muscle spasm and interruption of pain impulses to higher centers. Schroeder (1939) quotes McCrae and McDonald (1934) as doubting if either system (parasympathetic or sympathetic) is exclusively excitator or inhibitor these authors believe the two work together and with somatic nerves, to regulate bladder function. Yet they are of the opinion that the parasympathetics are more important and that they carry the stronger impulses.

Surgery. Jaboulay (1899) first directed attention to the fact that pain could be relieved by

surgery of pelvic sympathetics. Although Latarjet (1913) adequately described the pelvic sympathetics, the first presacral neurectomy was reported by Cotte (1925). Pieri (1926) tried Cotte's operation for relief of pain in tuberculous cystitis finding the surgery only partly successful. he next excised, with more satisfactory results, the lateral sacral chains at the level of the first sacral segment, and the communicating rami thereof. Learmonth (1930) employed Cotte's method in an attempt to correct neurogenic imbalance of the bladder. More extensive reports were made by Davis (1933, 1934) and Meigs (1940) on the relief of pelvic pain by presacral neurectomy. Schroeder (1939) enumerates several operative procedures for relief of bladder pain: excision of the superior

Fig. 2. Topography of the plexuses, ureter and ductus deferens immediately subperitoneal level. Showing the structures related to the pelvic colon and rectum, namely ureter, bladder, ligaments, and nerves. The parietal peritoneum of the lesser pelvis has been removed, and, additionally, the vesical part of the visceral peritoneum. The serous layer remains as the pelvic mesocolon, the covering of the colon and rectum, the rectovesical fascia and also as the bilaminar septum which descends between the bladder and rectum and rectum (fascia of Denonvilliers marked by arrow here and in Fig. 1). The ureter, ductus deferens, umbilical ligament (obliterated artery) and nerves have been freed from the thin stratum of subperitoneal areolar tissue.

Fig. 3 Relation of the hypogastric plexus to the terminal vesical plexus, and to the deeper rami derived from the sacropudendal plexus. The latter are situated at parietal level. Depicting the rectum urinary bladder ductus deferens, ureter pelvic autonomic nerves, and related structures. The following have been removed: pelvic colon proximal part of rectum (distal segment retracted) superficial leaf of autonomic nerves to the point of severance of the rectum (opposite fifth sacral vertebra). The nerves are followed toward the rectovesical excavation; the ductus deferens is mobilized as far as its point of junction with the seminal vesicle where the associated nerves lie within the rectovesical fold. The hypogastric and gluteal veins are exposed. The sacral sympathetic chain with communicating fibers from the second to the fourth sacral, is exposed, as is also the subjacent piriformis muscle. The layers shown are in succession: hypogastric and pelvic plexuses lodged chiefly in subperitoneal areolar tissue; heavy retroperitoneal connective tissue, upon which the visceral branches of the above named plexuses rest or through which they pass; visceral rami of the sacropudendal plexus of nerves; musculature (piriformis, passing from the sacrum through the greater sciatic foramen).

nerves and related structures they were prepared at life size.¹ An accessory illustration (Fig. 7) reduces the nerves to a schema. The diagrammatic sections (Figs. 8 and 9) are based upon a coronally cut pelvis of a second male specimen. Between the prostate gland and the rectum it descends as a partially fused plate of tissue termed Denonvilliers' fascia (arrow Fig. 1).²

OBSERVATION AND DISCUSSION

Peritoneum. The peritoneum is elevated by the obliterated hypogastric (umbilical) artery, slightly by the superior vesical branches derived therefrom and by the ductus deferens and ureter (Fig. 1).

The rectovesical fold is prominently tall; it is little more than apposed layers of peritoneum projects 1 centimeter backward from the bladder the excavation which it guards is 1.5 centimeters deep, measured from the edge of the fold to the depths of the rectovesical excavation. The transverse vesical fold is but a slightly elevated part of the peritoneum. The lateral umbilical fold has a maximum height of 1.5 centimeters (at the pubic crest), the fold is flattened so that its space opens lateralward.

The pelvic colon possesses a mesocolon which is 6 centimeters long where the colon reaches the midline over the fourth lumbar vertebra (Fig. 1); the mesentery becomes gradually shorter, being 2 centimeters long in the true pelvis opposite the first sacral vertebra; fixation occurs at the level

¹Comparable strata in the female pelvis were illustrated in an earlier article (Figs. 1 to 4; Carth, Anson, Ashley and Jones, 94).

²The reader is referred to the excellent article on Denonvilliers' fascia by Tobin and Benjamin in an earlier volume of this journal.

Fig. 4. Form and composition of the deeper leaf of plexus. Showing the pelvic plexus, the superficial leaf of which has been entirely removed to expose the deep layer of the plexus: a) tonomic plexus and the nerves contributing to its fabric. The nerves from the second to fourth sacral (erigens) remain intact, and the anterior continuation of the pelvic autonomic plexus has been followed ventralward to the bladder seminal vesical, and prostate. The rectum, transected at coccygeal level, has been retracted. The large vein which verlay the first sacral nerve (in Fig. 3) has been removed. The superficial group of vessels is exposed (superior and middle vesicular arteries from the obliterated hypogastric) the deep vessels (hypogastric and external iliac) remain covered by the heavy lamina of pelvic fascia. The main mass of the plexus is parietal in position, resting upon those which, in turn, lies immediately upon the obturator fascia.

of the ridge between the second and the third sacral segments. The pelvic colon is constricted through the greater part of its length. The rectum is similarly constricted as it lies in front of the third and fourth sacral pieces. It widens slightly in front of the fifth, and further enlarges as it passes distalward beyond the area of vertebral relationship. The narrowed anal canal leaves the rectum at an angle of almost 90 degrees. The three portions of the tube are then, related to one another as the parts of a letter Z reversed.

Subperitoneal structures The heavier retroperitoneal tissue which ascends on either side of the urinary bladder as a wing to iliac level, in projecting backward forms the plate of tissue over which the peritoneum is draped to produce the rectovesical fold (Fig. 2).

The observations on the general arrangement of subperitoneal tissue are in accord with those made earlier on the female (Curtis Anson, and

Benton 1940) Vessels in the category of the hemorrhoidal are lodged in a fine areolar layer which is immediately subperitoneal, autonomic nerves coursing to viscera are next in level, becoming more superficial as they approach the organs. Parietal vessels are placed in the heavy connective tissue which is clearly "parietal" and with them are situated visceral rami most deeply placed, and actually retrofascial, are the elements of the sacral and lumbar plexuses, from which latter communicating rami are sent through the heavier retroperitoneal tissue to reach the autonomic plexuses near the bladder and rectum.

The ductus deferens, ureter and accompanying nerves lie within a thin areolar layer with the middle hemorrhoidal and associated sympathetic plexus (which give off rectal, vesical, and prostatic sets of nerves). Still covered by tissue of areolar character but evident as elevations, are the "obliterated" hypogastric artery (lateral umbilical ligament) and its derived superior vesical

Fig 3 Parasympathetic origin of the rami contributory to the pelvic plexus, and deep structures related to the latter. The deep relations of the pelvic plexus, shown by removal of the plexus and the heavy retroperitoneal tissue which partially invests it. The transected parasympathetic nerves (visceral rami of the pudendal plexus) remain connected with the sacral plexus; the distal continuations of the autonomic nerves have been cut as they disappear beneath the prostate and seminal vesicle. The connections between the inferior hypogastric plexus and the pelvic plexus have been severed along the inferior margin of the former. All of the retroperitoneal connective tissue has been removed, exposing the endopelvic fascia, the vessels and nerves to the pelvic viscera and parietes, and to the lower extremity. The connective tissue has been removed from the greater sciatic foramen to expose the full course of the nerves contributory to the sacral and pudendal plexuses and the larger vessels as they leave the pelvis. The superior fascia of the pelvic diaphragm has been removed, exposing the levator ani muscle.

branches. The outlines of the gluteal obturator middle hemorrhoidal and pudendal vessels are masked by the heavy retroperitoneal layer.

Nerves. Most important is the position of the several sympathetic plexuses (Fig 2 cf Fig 7). They are parietal in position; they do not immediately surround the organs as familiar textbook illustrations would lead one to believe. Actually the large middle hemorrhoidal is actually 5.5 centimeters distant from the rectum; it sends numerous rami to the rectum, these passing posteriorly over an area bounded by the line at pelvic mesocolic attachment (above) and the line projected (below) from the superior surface of the urinary bladder. In the erect body their direction would be horizontal, while that of the trunk from which they are derived would be vertical.

The deeper structures are chiefly related to the nerves of the intermediate and deep leaves (Fig 3). The intermediate leaf consists of the parasympathetic fibers of the second third and fourth sacral and sympathetics which enter these just lateral to the chain ganglia. The parasympathetics (nervus ergens) intercommunicate forming a small plexus which makes up a deep leaf. The two layers meet approximately 3 centimeters lateral to the rectum. Some of the fibers of the parasympathetic derived from the fourth sacral diverge medially to enter the wall of the rectum. The intermediate leaf is separated from the deep (sacral plexus) by the large hypogastric vein and its gluteal tributary. The vein in turn crosses the piriformis muscle obliquely. From the large ganglion resting upon the lateral surface of the body

urethra to innervate those structures. There is a separate group of small fibers which passes into the region of the seminal vesicle. Some fibers detach themselves from the plexus to supply the terminal portion of the rectum.

The superiorly located fibers of the plexus pass beneath the seminal vesicle and the crooked portion of the ductus deferens to enter the wall of the bladder. The lowermost, as previously mentioned, enter the rectum, and intermediate fibers continue to the prostate and membranous urethra.

The distance from the mid point of the plexus to the lateral rectal wall is 3.5 centimeters. The length of the Y-shaped plexus is 8 centimeters (to the nerves at the prostate).

The parasympathetic nerves are five in number (Fig. 5) severed at the point of entrance into the plexus. The cranial two arise from the junction of the second and third sacral, the third arises from the third sacral, the fourth nerve from the fourth sacral entirely, and the fifth from the junction of the third and fourth. The plexus is prolonged between the rectum and prostate; the plexus was previously described as an intermediate group of nerves leaving the plexus and entering the prostate, the inferior aspect of the bladder and the seminal vesicles. The inferior or caudal group of nerves leaves the plexus to enter the ampulla of the rectum as three or four stems of gross dimensions.

Vessels. The hypogastric artery and its branches and corresponding veins lie deep to the fascial layers which house the autonomic nerves (Fig. 5). The most superiorly placed vessels are the external iliac artery and vein. Next is the umbilical artery with its four vesical branches, all of which course first toward the superior surface of the bladder, some then passing to the inferior. The vesical arteries are lodged in an intermediate layer of connective tissue which covers the deep vessels and remains entirely separate from them. The small deferential artery takes origin from the lowermost of the vesical arteries, the ureteric artery also in this layer arises from the small vesicular branch just above the one which gives origin to the deferential. Another small artery passes directly through the plexus to enter the tip of the seminal vesicle. The obturator arises by a common stem with the umbilical, the gluteals descending leave the pelvis above and below the piriformis muscle. The inferior gluteal artery gives rise to the internal pudendal just before it leaves the pelvis.

The vessels are internal to the endopelvic fascia (Figs. 5 and 6).

Fig. 7. Diagram of the pelvic plexus, showing origin and distribution of the chief components, and their gross interrelationships. Medial aspect. The hypogastric plexus is shown intact in its curving course to the urinary bladder but has been cut away in that part which, overlying the pelvic plexus, contributes to the hemorrhoidal plexus. Between these two, and lateral to them, the fibers derived from the sacral nerves are shown streaming toward the bladder, prostate, anal canal, rectum, etc.

The endopelvic fascia. The so-called endopelvic fascia is actually aponeurotic in nature. Continued upon the levator ani and coccygeus muscles the endopelvic fascia becomes diaphragmatic fascia (Fig. 6). Over the upper part of the obturator internus muscle it is parietal and when reflected from the pelvic diaphragm to the rectum and bladder it becomes visceral (cf. figures in Curtis Anson and Beaton, 1940).

It is clear, then that the relations to fascial levels are of fundamental importance. In the heavy retroperitoneal layer is located the large pelvic plexus, with its vesical and prostatic continuations (Fig. 4). Into this layer sink the originally superficial fibers of the inferior hypogastric plexus (Fig. 2) and to it ascend the visceral rami originating from the sacral plexus of nerves (Figs. 3 to 5). In dissections this set of relationships is strikingly demonstrated when the heavy stratum is reflected (Fig. 3) as they enter the pelvis from above the sympathetic fibers are situated just beneath the serous layers and upon the heavy

urethra to innervate those structures. There is a separate group of small fibers which passes into the region of the seminal vesicle. Some fibers detach themselves from the plexus to supply the terminal portion of the rectum.

The superiorly located fibers of the plexus pass beneath the seminal vesicle and the crooked portion of the ductus deferens to enter the wall of the bladder. The lowermost as previously mentioned, enter the rectum and intermediate fibers continue to the prostate and membranous urethra.

The distance from the mid point of the plexus to the lateral rectal wall is 3.5 centimeters. The length of the Y-shaped plexus is 8 centimeters (to the nerves at the prostate).

The parasympathetic nerves are five in number (Fig. 5 severed at the point of entrance into the plexus). The cranial two arise from the junction of the second and third sacral; the third arises from the third sacral; the fourth nerve from the fourth sacral entirely, and the fifth from the junction of the third and fourth. The plexus is prolonged between the rectum and prostate; the plexus was previously described as an intermediate group of nerves leaving the plexus and entering the prostate, the inferior aspect of the bladder and the seminal vesicles. The inferior or caudal group of nerves leaves the plexus to enter the ampulla of the rectum as three or four stems of gross dimensions.

Vessels. The hypogastric artery, and its branches and corresponding veins lie deep to the fascial layers which house the autonomic nerves (Fig. 5). The most superiorly placed vessels are the external iliac artery and vein. Next is the umbilical artery with its four vesical branches, all of which course first toward the superior surface of the bladder, some then passing to the inferior. The vesical arteries are lodged in an intermediate layer of connective tissue which covers the deep vessels and remains entirely separate from them. The small deferential artery takes origin from the lowermost of the vesical arteries; the ureteric artery also in this layer arises from the small vesicular branch just above the one which gives origin to the deferential. Another small artery passes directly through the plexus to enter the tip of the seminal vesicle. The obturator arises by a common stem with the umbilical; the gluteals, descending leave the pelvis above and below the piriformis muscle. The inferior gluteal artery gives rise to the internal pudendal just before it leaves the pelvis.

The vessels are internal to the endopelvic fascia (Figs. 5 and 6).

Fig. 7. Diagram of the pelvic plexus, showing origin and distribution of the chief components, and their gross interrelationships. Medial aspect. The hypogastric plexus is shown intact in its curving course to the urinary bladder but has been cut away in that part which, overlying the pelvic plexus, contributes to the hemorrhoidal plexus. Between these two, and lateral to them, the fibers derived from the sacral nerves are shown streaming toward the bladder, prostate, anal canal, rectum, etc.

The endopelvic fascia. The so-called endopelvic fascia is actually aponeurotic in nature. Continued upon the levator ani and coccygeus muscles the endopelvic fascia becomes diaphragmatic fascia (Fig. 6). Over the upper part of the obturator internus muscle it is parietal and when reflected from the pelvic diaphragm to the rectum and bladder it becomes visceral (cf. figures in Curtis Anson and Beaton, 1940).

It is clear, then, that the relations to fascial levels are of fundamental importance. In the heavy retroperitoneal layer is located the large pelvic plexus, with its vesical and prostatic continuations (Fig. 4). Into this layer sink the originally superficial fibers of the inferior hypogastric plexus (Fig. 2) and to it ascend the visceral rami originating from the sacral plexus of nerves (Figs. 3 to 5). In dissections this set of relationships is strikingly demonstrated when the heavy stratum is reflected (Fig. 3) as they enter the pelvis from above the sympathetic fibers are situated just beneath the serous layers and upon the heavy

Fig. 8.

Figs. 8 and 9. Diagrams of the location of autonomic nerves, showing relations of the main sets to the subserous strata of the pelvis. Coronal sections in anterior view. The chief elements of the broad pelvic plexus are lodged in the heavy layer of retroperitoneal tissue (at level 3) the hypogastric plexus and its subdivisions are situated in thinner layer internal or medial thereto (level 2) while the sacral plexus and its fibers to pelvic musculature are located

Fig. 9.

located external or lateral to retroperitoneal layer (at level 4). Posteriorly to the greater sciatic foramen its nerves (at site of crosses in Figure 9) contributing chiefly to the formation of the sciatic nerve rest upon the fascial covering of the piriformis muscle.

retroperitoneal layer on the contrary the para-sympathetics, originating behind, are located beneath the heavy layer and upon the endopelvic fascia as the latter covers the parietal musculature (obturator internus). All of the fibers from these two sources which ultimately reach the urogenital organs enter and course through the heavy retroperitoneal layer this would be the expected arrangement, since the strong fibrous layer becomes the immediate coat of each of the pelvic organs, merging with the sheath derived from the endopelvic fascia.

Sciatic foramen. The sciatic foramen is bounded anteriorly by the arching border of the endopelvic fascia. Through it passes the superior gluteal, inferior gluteal, and internal pudendal arteries, and the lumbosacral nerves which converge to form the sciatic. The parasympathetic nerves (nervus erigens) also visible, arise just before the sacral trunks join. The most caudal of the nerves arising from the sacral plexus is the nerve to the levator ani.

Ischiorectal fossa. The visceral ramal derived from the sacropudendal plexus are, then, prominent as a group where they leave the sacral nerves at the archiform border of the sciatic foramen (Figs. 5 and 6). But, within the ischiorectal fossa, comparable fibers to the erectile bodies are difficult to segregate they tend to follow inconspicuously the pudendal nerve.

The ischial spine constitutes the serviceable landmark around it the obturator internus disappears as it leaves the pelvis attaching to the ischial spine are the posterior end of the iliopectineus part of the levator ani, and the lateral insertion of the coccygeus muscle which forms the posterior fourth of the pelvic diaphragm.

CONCLUSIONS

The autonomic nerves of the pelvis make up a set of neural sheets which not only are of gross dimensions, but which are of such position and form as to be demonstrable in the form of subperitoneal bands with predictable relationships to bony landmarks, to large blood vessels and to viscera. The large bands and the lesser contributory fibers as they course from root or plexus of origin to area of visceral termination, are either lodged within readily dissectable fibrous laminae or situated at levels either immediately superficial or deep to such laminae.

The chief layer is that which is most marked as it extends upward along the pelvic wall after having formed a strong sheath for the urinary bladder and associated structures. It is the layer which transmits, also, the blood vessels of visceral supply. Resting upon this stratum, at subperitoneal level, is an areolar tissue in which is situated most of the nerves of supply to the rectum under the same stratum are placed the sacropudendal plexus

and the rami which pass therefrom to the large plexus in the intermediate layer. The intermediate is therefore, the chief one of the three into the pelvic plexus which it contains pass rami from the sympathetic and parasympathetic plexuses in layers on its internal and external aspects.

In the superficial (internal) layer of areolar tissue course the hypogastric plexus that portion of the pelvic plexus which sends rami chiefly to the rectum, the contributory mesenteric plexus, and the ductus deferens. These are structures which are subperitoneal or were originally mesenteric (when, embryonically a mesorectum existed). Being placed immediately beneath the serous lining of the pelvic cavity they elevate the peritoneum—but less markedly than do the umbilical ligaments (Fig. 1).

Topographically, the inferior mesenteric plexus lies anterior to the ureter following it closely the inferior hypogastric plexus and its pelvic prolongation lie posterior to the ureter between the latter and the rectum. The main mass of the plexus courses in a curving line—concave anteriorly—between the first piece of the sacrum and the rectovesical fold.

In its distal portion the fibers spread out principally on the superior surface of the bladder behind, groups of fibers radiate to the rectum a strong set forming a secondary plexus close to the rectal wall. Altogether these plexuses and derived fibers of visceral supply cover a semicircular area whose posterior boundary follows the contour of the rectum and that of the sacrum against which the latter rests (Fig. 2).

Embedded in the heavy layer of true retroperitoneal tissue are the deeper elements of the autonomic supply (Fig. 4). The anterior boundary of this set of fibers coincides with that of the more superficially situated hypogastric plexus, but its form is strikingly different. It assumes the configuration of a broad ribbon wider at the proximal and distal ends than in the middle two-fourths of its extent. Its widest portion is proximally situated, where visceral rami are contributed by the sacral nerves (Figs. 3 and 4) upon it converge, distally the fibers of the vesical portion of the pelvic plexus, to produce a second broadening terminal distribution to the bladder prostate, seminal vesicles and rectal ampulla is also instrumental in causing the widening of the band which occurs at its anteroinferior end. In an anteroposterior direction this intermediate band is somewhat more extensive than the superficial the former is carried to the sacrum (the points of origin of the nerves Fig. 4) the latter to the rectum (the visceral area of supply Fig. 2). The

intermediate band is the longer of the two owing to the fact that the greater bulk of its fibers are supplied, not to the rectum in the sacral curve, but to the bladder prostate, anal canal, as these rest upon the pelvic floor.

The third and deepest of the three neural strata is that composed of the proximal portions of the visceral rami of the pudendal plexus and the sacral plexus, from which the rami are derived. Because the branches quickly enter the pelvic plexus—merging on the latter's deep aspect, and within the substance of the heavy retroperitoneal tissue—this third layer is but slightly longer than it is wide. It overlies the second to fourth nerves (from which it arises) being thus caudally placed, its long axis is at almost a right angle to that of hypogastric plexus in the superficial, or first layer. The upper cords of the sacral plexus, and the lumbosacral cord from the abdominal level rest in similar tissue upon the piriformis muscle the pudendal rami leave the nerve trunks near the point where the latter emerge through the greater foramen en route to the gluteal region. As the rami course toward the pelvic plexus, they come to lie upon the fascia covering the obturator internus.

The sympathetic fibers which descend into the pelvis from abdominal level form the mesenteric and hypogastric plexuses the parasympathetic fibers, commonly described as forming a nervus ergens, enter the pelvic plexus as a set of autonomic nerves. All fibers, so far as gross examination reveals are mixed in the broad ribbon of nervous tissue which is termed pelvic plexus. Therefrom fibers stream toward the several pelvic organs, a degree of stratification obtaining in the distribution to mesenteric and to retroperitoneal viscera for the most part nerves to the rectum pass, on immediately subperitoneal or superficial, level, from the anterior border of the plexus backward in radiating fashion to the pelvic portion of the digestive tube similarly nerves to the urinary bladder subjacent prostate gland to the seminal vesicles, lodged, at the intermediate level in the heavy sheath of retroperitoneal tissue stream downward and forward to the organs named—all ultimately supported by the funnel-shaped pelvic diaphragm.

From the surgical standpoint the following conclusions seem warranted sympathetic fibers may be transected by presacral neurectomy parasympathetic elements left untouched by the same procedure in both abdominal and perineal approach to the rectum (in high operation for carcinoma) the chief portions of the autonomic plexuses are removed by safe distance, from the

surgical field—being parietal in position in the dorsal portion of the pelvic cavity in any of the regular approaches (pubic, transsymphyseal perineal or rectal) to the urinary bladder or prostate gland the disturbance of tissue would occur in areas where concentration of autonomic fibers is minimal—behind the main plexiform aggregations in anterior approach, and above them in inferior entrance to the pelvis. However in wide removal of carcinomatous lymphatic and associated fibrous tissue within the pelvis, the areas where nerves are abundant would be affected the plexuses, in resting upon the hypogastric artery and its important branches, are situated between the peritoneum and the lymphatics, since the latter are closely associated with the blood vessels.

In summary, then, it may be said that the nerves of supply to the pelvic organs are so disposed as to be naturally protected from damage in urological surgery. In spreading out upon the bladder from behind and above, terminal fibers are fewest on the anterior (apical) and inferolateral portions in supplying the rectal and anal parts of the canal the nerves do not descend with the tube in the form of an investing net, but, approaching the canal from the side they end in relation to local

segments. Finally it may be pointed out that so great is the intermingling within the plexus of fibers derived from various sources that localized excision or extirpation would be expected to result in relatively slight interference with function of a pelvic organ.

STUDIES ON EXOPHTHALMOS PRODUCED BY THYROTROPIC HORMONE

II Changes Induced in Various Tissues and Organs (Including the Orbit) by Thyrotropic Hormone and Their Relationship to Exophthalmos

BROWN M DOBYNS M D., Rochester Minnesota

IN a preceding publication (21) the development of exophthalmos in thyroidectomized animals receiving various preparations of thyrotropic hormone was described. Antuitrin T produced a striking degree of exophthalmos but in many animals it also produced profound myasthenia and loss of weight in spite of the absence of the thyroid. A so called purified preparation however failed to produce exophthalmos, toxic manifestations or loss of weight but did cause some hyperplasia of the thyroid of intact animals. A crude thyrotropic preparation which was prepared in a manner similar to that of the so called purified preparation but without the additional efforts at purification and which was administered in quantities equal in thyroid stimulating effect to the purified product caused exophthalmos. This exophthalmos, however, was less striking than that produced by antuitrin T. Toxic effects and loss of weight from the crude preparation were minimal. The specific metabolic principle, a fraction of thyrotropic hormone did not produce exophthalmos and was known from the work of others (8, 18, 19) not to produce thyroid hyperplasia.

The tissues of these animals, from which accurate data on exophthalmos have been obtained have furnished the source of material for this report.

LITERATURE

In 1936 Smelser (43) described an infiltration of a stainable material accompanied by nests of lymphocytes and edema in the extraocular muscles and orbital fat of guinea pigs rendered exophthalmic by thyrotropic hormone. This was confirmed by Paulson (37, 39) who also described loss of striations in the extraocular muscles. Smelser (44, 46) concluded in later papers that the changes in muscle were confined to the connective

tissue between the muscle fibers. Paulson (38, 39) later found muscle degeneration and round cell infiltration in cardiac and other skeletal muscles. He reported that this change was most striking in the first few days of administration of thyrotropic hormone and that it occurred regardless of the presence or absence of the thyroid. The cellular reaction was found to be much milder degree in normal and thyroidectomized control animals.

Aird (12) demonstrated varying degrees of cellular reaction in extraocular muscles and edema of orbital tissue with several thyrotropic preparations. Brock (13) although primarily interested in cellular infiltration in cervical sympathetic ganglia mentioned the feature in muscle. Smelser (44) and Paulson (37) reported that the muscle changes might not be present although exophthalmos developed. Paulson (38) could not demonstrate an appreciable increase of the water content of muscles but in agreement with Smelser (44, 47) he did show an increase of the water content and volume of the orbital tissue masses.

Smelser (45) after finding an edematous infiltration in the connective tissue of fat in the orbit studied other fat depots. Cervical and axillary fat were unaffected but the fat about the kidneys, ovaries and ureters appeared to be involved by the same process although to a much less striking degree than in the orbit. These observations on fat depots other than the orbit have not been confirmed. Since the investigation described in this publication was carried out Smelser (47) has described an increase of the residue of the orbital tissues after the extraction of fats and water in animals that have been given thyrotropic hormone.

The significance of the cellular reaction elicited by thyrotropic hormone in fat, connective tissue and muscle is not understood. Just what the relationship of these tissue changes may be to the exophthalmos that develops is not certain. A cellular reaction accompanied by edema and fibrosis in orbital tissues of patients suffering from

Abridgment of thesis submitted by Dr. Dobyns to the Faculty of the Graduate School of the University of Minnesota. In partial fulfillment of the requirements for the degree of Ph.D. in Surgery. Work done at the Institute of Experimental Medicine, in the laboratory of Dr. George M. Huggins.

Fig. 1. Left, perinephric fat from normal control guinea pig. Right, perinephric fat from guinea pig treated with antuitrin T. Note the apparent replacement of opaque fat by a more transparent gelatinous material (transillumination X).

malignant exophthalmos has been described by Naffziger and many others (11, 12, 13, 17, 22, 23, 27, 31, 32, 33, 36, 43, 44, 48). It may be of interest that Haik (27) recently reported "extreme fatty metamorphosis of the liver" and cloudy swelling in the kidney in a case of malignant exophthalmos at necropsy. Naffziger (34) reporting on muscle biopsies from locations other than the orbit, did not observe the muscle changes usually encountered in the orbit.

EXPERIMENTS PRELIMINARY TO THIS STUDY

In preliminary experiments, examination of tissues of animals receiving antuitrin T confirmed these reports of the presence of round cells in orbital tissue, to a lesser degree in muscles, and in many of the fat depots throughout the body. In other preliminary studies it was found that these cells contained many fine droplets of fat. Likewise muscle fibers throughout the body and the cells of the liver and the kidneys were loaded with fat droplets after thyrotropic hormone had been administered.

PURPOSE OF THIS STUDY

The purpose of this study was to investigate the possibility of a general systemic cellular reaction in guinea pigs given antuitrin T and to correlate these reactions with those known to occur in the orbit associated with exophthalmos. In addition observations were made of the reactions which ensued in animals when they were given various other crude and so called purified thyrotropic preparations. Since the unit potencies of these preparations differed from that of antuitrin T

any comparison of their effectiveness with that of antuitrin T was not undertaken.

METHODS

The several groups of animals that had received various thyrotropic preparations for varying lengths of time were as follows:

A. Antuitrin T was administered in daily amounts containing 25 Junkmann-Schoeller units¹ to 15 thyroidectomized animals, 7 of which had also been orchectomized. Four intact animals also received this product. The period of administration was from 3 to 32 days.

B. The solvent for antuitrin T including the preservative but without the pituitary ingredient, was given in comparable daily doses as a control to 4 intact animals.

C. Five intact animals with comparable body weights were fasted, to induce a loss of weight like that sustained by some of the animals receiving antuitrin T. These served as controls for changes sustained solely from loss of body weight.

D. A so called purified thyrotropic factor was given to 8 thyroidectomized animals in daily amounts containing 2.5, 5.0, and 10.0 Rowlands-Parkes units² for periods of from 7 to 39 days.

E. Crude thyrotropic preparation was given in daily amounts containing 5 and 10 Rowlands-Parkes units to 10 thyroidectomized animals for periods of from 8 to 24 days.

F. The specific metabolic principle, which is a fraction of a thyrotropic preparation and which failed to produce thyroid hyperplasia, was administered in daily amounts of 1 cubic centimeter (later raised to 2 cubic centimeters) to 4 thyroidectomized animals for periods of 6 to 8 days.

Most of the animals were killed by ether. As a control procedure, a few animals were killed by lethal doses of pentobarbital sodium. Axillary, cervical, periurethral, orbital and testicular fat and temporal, cardiac, and extraocular muscles were removed and fixed in 10 per cent solution of formalin. The entire orbital contents were dissected from the bony orbit as a single unit. This mass of tissue was fixed and sections were made through the entire substance just posterior to the globe so that a cross section of all retrobulbar tissues was obtained. Sections were made of the liver, kidney, spleen and representative lymph

¹ A unit is that amount of hormone which, injected daily for three days, causes 25% of animals (40-50), recognizable hypertrophy of the epithelium and disappearance of colloid in the thyroid of guinea pigs 250 to 350 gm in weight (Potency as based on assay by manufacturer).

² A unit is that amount of extract which gives daily for 5 days will cause the thyroids of mature female guinea pigs weighing 300 grams to double their weight or attain weight of 60 milligrams. (Rowlands-Parkes were described as weighing approximately 30 milligrams (4).) (Potency was based on assay by manufacturer and confirmed by the author).

Fig. 2. Changes induced in the testicular fat tab of a thyroidectomized guinea pig by 0.5 cubic centimeters of antuitrin T daily for 3 days (hematoxylin and eosin $\times 118$)

Fig. 3. Changes induced in the testicular fat tab of a thyroidectomized guinea pig by 0.5 cubic centimeters of antuitrin T daily for 13 days (hematoxylin and eosin $\times 118$)

nodes. In some animals sections of the ureter and of the small intestine were prepared.

Two techniques for histologic preparation were employed. Frozen sections were cut and stained with scarlet red and counterstained with hematoxylin. Paraffin sections were stained with the routine hematoxylin and eosin stains. In instances in which connective tissue changes were observed Mallory Heidenhain and van Gieson stains were applied. In some instances mucicarmine stains were used.

At the time of thyroidectomy and orchectomy biopsies were taken of cervical and testicular fat. These tissues were subsequently contrasted with those obtained from the same animals after thyrotropic hormone had been given to them.

The changes in each tissue were studied and recorded by grading the degree of change on the basis of 1 to 4 (1 being the smallest discernible change and 4 being the most striking degree of change).

RESULTS

A. Gross changes induced in tissues by thyrotropic hormone preparations. Antuitrin T produced the most striking gross changes in animals regardless of the presence or absence of the thyroid. Fat from most of the fat depots had a redder appearance and possessed a more firm and rubbery consistency than did fat of normal animals. This gross change was most striking in the first few days of administration of antuitrin T. After longer periods the fat depots were extremely depleted of fat and, in the place of the fat there was found a translucent gelatinous material (Fig. 1). The most striking changes in fat occurred in animals which had lost the most

weight. Although some of the animals treated with antuitrin T had lost considerable weight in many cases the volume of the gelatinous fat depots was not materially decreased. This was in contrast to the markedly decreased volume of the fat depots of the fasted control animals which had lost comparable amounts of weight. In the fasted guinea pigs which had lost considerable weight and possessed depleted fat depots, the fat remained soft and showed little if any of the gelatinous character. The fat in animals which were given the preparations, other than antuitrin T did not differ grossly from the normal.

In animals which had received antuitrin T for only a few days the skeletal muscles were rather pale and had a tendency to tear easily when stretched. The livers of such animals were extremely pale slightly enlarged and very friable. But after more prolonged administration of antuitrin T the skeletal muscles and liver returned to a more normal color and consistency. Color changes similar to those in the liver were induced in the kidneys.

In the animals given antuitrin T the connective tissue septa of the harderian glands were edematous and appeared as dark partitions between the lobules, much in contrast to these septa in normal glands.

In the animals which received the crude thyrotropic preparation the connective tissue septa of the harderian glands were less edematous than those in animals receiving antuitrin T. In certain of this group which gained less weight the livers were rather pale and mottled and the fat depots were abundant occasionally more glossy and edematous than normal.

Fig. 4. a, left, Axillary fat of normal guinea pig. b, Changes induced in the axillary fat of a thyroidectomized

guinea pig by 0.5 cubic centimeter of antuitrin T daily for 3 days (hematoxylin and eosin $\times 18$)

The tissues of the animals which received the solvent for antuitrin T and of those which received the so called purified thyrotropic factor or the specific metabolic principle did not show any of these gross changes such as occurred in the animals receiving antuitrin T or the crude thyrotropic preparation.

B Microscopic changes induced in tissues of animals receiving antuitrin T. The most consistent change observed in the tissues of animals receiving antuitrin T was the appearance of large numbers of mononuclear and polymorphonuclear leucocytes containing fat droplets a condition not ordinarily seen in such cells of control animals. This cellular reaction was accompanied by varying degrees of edema. These fat-containing cells occurred not only in the orbital tissue but throughout the connective tissue generally. Fat tissues throughout the body were markedly

altered (Figs. 2, 3, 4, and 5). The thin septa of connective tissue fibers between the fat cells were three to four times their normal thickness. Clusters of large and small mononuclear and polymorphonuclear leucocytes had infiltrated into these thickened septa. In some areas where the reaction was extreme, a homogeneous, faintly staining material had formed within these connective tissue spaces to such an extent that the fat cells appeared to be floating in a matrix (Figs. 2 and 4). This cellular reaction resembled very closely the histologic pattern of the reparative processes seen in fat necrosis accompanying traumatized tissue.

In animals given antuitrin T for short periods, there were more polymorphonuclear cells containing more fat droplets and there was more edema but only slight proliferation of connective tissue. In animals given this preparation for

Fig. 5. a, left, Orbital fat of normal guinea pig. b, Changes induced in the orbital fat of a thyroidectomized

guinea pig by 0.5 cubic centimeter of antuitrin T daily for 9 days (hematoxylin and eosin $\times 8$)

Fig. 6. Fat laden skeletal (temporal) muscle fibers of an intact guinea pig that had received 0.5 cubic centimeter of antuitrin T daily for 2 days (scarlet red and alum hematoxylin $\times 96$).

longer periods, there were fewer polymorphonuclear cells, more lymphocytes, more large macrophages and fibroblasts and more collagenous connective tissue but less edema.

In sections of the cardiac and skeletal muscles of injected animals there was but little cellular infiltration although there was more than in sections of normal muscle. In preparations stained with hematoxylin and eosin a mild degenerative process of muscle fibers characterized by a loss of striations and a granular appearance of the fibers, was evident. This occurred in a spotty manner without apparent relation to the blood supply or to any other recognized anatomic feature.

These changes in muscle took on added significance when fat stains were applied to these same muscles for it was found that the fibers, in the same spotty fashion, were loaded with tiny droplets of fat (Fig. 6). In some sections of a single fiber the fat was in great abundance while in other places along the same fiber relatively little change from the normal was found. The degree of change in various muscles in the same animal showed considerable variation. The extraocular muscles when studied in this way were almost always found to contain more fat than any other muscles. At times the lymphocytes and the large macrophages were more abundant about those portions of the muscle containing the most fat; however in other instances the most affected muscles contained no new cellular elements. These macrophages and lymphocytes were always most abundant in connective tissue bordering muscle fibers or in perivascular locations.

Fig. 7. a, left, Normal harderian gland ($\times 35$). b, Marked edema of the connective tissue around and within the harderian gland of a thyroidectomized guinea pig in which exophthalmos had been induced by administration of antuitrin T ($\times 35$).

The same general trend of the reaction that was observed in connective tissue and fat, namely, less fat in tissue macrophages as treatment continued, occurred also in muscle tissue. Animals treated for a short time contained much more fat in the muscle fibers than those treated for longer periods. A very close correlation was noted between the presence of fat in the muscle fibers and the degree of myasthenia produced by antuitrin T. This correlation held true even in the animals

Fig. 8. Edema in skeletal (temporal) muscle following the administration of 0.5 cubic centimeters of antuitrin T daily for 13 days to a thyroidectomized guinea pig (hematoxylin and eosin $\times 140$). This is an example of a striking degree of edema in muscle. There was rather high grade edema of connective tissue (see Figs. 3 and 4) throughout the body of this animal as well as marked exophthalmos. The temporal muscle was chosen because by its position edema is least likely to develop on the basis of dependency.

treated for longer periods when fat in muscle was rarely found and myasthenia was infrequently observed.

The large, pale, friable livers observed in the animals receiving antuitrin T for a short time contained relatively large amounts of fat but the livers of those animals given the preparation for longer periods contained less fat. In those animals in which the kidney was studied the droplets of fat were present in cells of the tubular epithelium. However here again the amount of fat present was readily correlated with the duration of the injections and corresponded well with the presence of fat in muscle and in liver. Fat droplets were seen too in the large reticuloendothelial cells of the lung in the spleen and in lymph nodes of animals which possessed pronounced changes in fat elsewhere in the body. Likewise the epithelial cells of the ileum and bronchi contained tiny droplets of fat in their cytoplasm. Excessive quantities of fat were found in the lacteals of the small intestine.

Edema in the orbit was most easily recognized in the septa of the hardenian glands (Fig. 7). It was present, too, in the connective tissue of the fat in the orbit (Fig. 5) and in other fat depots of the body (Fig. 3). In a few animals which had had striking exophthalmos, extensive edema had developed in the temporal muscle (Fig. 8). In many animals edema was either present in small amounts or absent entirely from these muscles.

The infiltration of a homogeneous, faintly staining intercellular substance in connective tissue especially in adipose tissue, appeared quite consistently not only in the orbit but elsewhere in the body (Figs. 2, 3, 4, and 5). Mucicarmine stains did not reveal the presence of mucin but van Gieson and Mallory Heldenheim techniques indicated that this material was probably collagen of young connective tissue. This homogeneous material was associated with the cellular reaction described previously and was usually most prevalent after a period of treatment when the acute phase of the cellular reaction was subsiding. The effect of antuitrin T on the tissues of intact animals is the same as seen in thyroidectomized animals when one considers equal periods of treatment. The general impression was that the edema that developed in normal animals was somewhat less than that in thyroidectomized animals.

The tissues of the group of animals which received the solvent for antuitrin T did not sustain these histologic changes. This, therefore would seem to eliminate the possibility that the solvent or preservative was the causative factor in pro-

ducing the tissue changes. Exophthalmos, it will be recalled did not develop in this group of animals.

Because the most striking changes in fat occurred during the early administration of antuitrin T and because it was during this period that the animals lost the most weight it seemed advisable to know whether phagocytosis of fat occurred in animals which lost weight rapidly for other reasons, for example, fasting. It is known that fasting is accompanied by a rapid mobilization of fat from depots and that this fat is subsequently found in abundance in the liver.

In the fat depots of fasted animals, in which the fat was extremely depleted nuclei of fat cells persisted and there was a relative increase of connective tissue with few lymphocytes, macrophages, and polymorphonuclear leukocytes. Fat droplets were occasionally seen in these cells but in negligible amounts when the fasted animals were compared with animals which had received antuitrin T. In no instance was this finding more than minimal in the fat depots of fasted animals.

The presence of fat in muscles was also found in fat-stained preparations from fasted animals but to a very mild degree. There was also a slight amount of edema in the connective tissue of some of the fasted animals.

It has been shown by the author in experiments described elsewhere (20) that thyroidectomy alone was not followed by any appreciable increase of cellular elements or edema in connective tissue.

C. Microscopic changes induced in the tissues by other thyrotropic preparations. The purified thyrotropic factor in the amounts administered, resulted in the appearance of some fat in the liver but no increase of cellular elements in connective tissue was recognized and phagocytosis of fat by such cells was not graded more than 1. In the hematoxylin and eosin preparations there was some evidence of an increase of the number of macrophages but the deposition of new connective tissue was not demonstrable. Muscle degeneration however occurred to an appreciable degree (grade 3) in only one animal, which was an exception and in which some exophthalmos had developed. Edema in all tissues including the orbit was more noticeable than in thyroidectomized controls, and a very slight increase in connective tissue had been induced.

Generally speaking the tissue reaction in the animals given the crude thyrotropic preparation in the amounts indicated was less pronounced than that found in animals given antuitrin T. However it was more marked than the equivocal

DOBYNS STUDIES ON EXOPHTHALMOS FROM THYROTROPIC HORMONE 615

changes induced by the so called purified thyrotropic preparation. The degree of edema in these animals resembled that of animals treated with antuitrin T and occurred throughout all the connective tissues examined. There was an abnormal increase of the number of tissue macrophages but polymorphonuclear cells were rarely seen. The presence of fat droplets in tissue macrophages, however, was considerably less than in animals given antuitrin T. In only about a half of the animals such intracellular fat was demonstrable however it was relatively marked in a few animals which had gained less weight. The appearance of fat droplets in muscle fibers was moderate in most animals. It was not demonstrable at all in one animal which was conspicuously different in other respects. The abnormal presence of fat in other organs was variable and the homogeneous faint staining material was not found in these animals.

In animals which received the crude thyrotropic preparation in the amounts indicated less striking exophthalmos developed than in animals treated with antuitrin T. Edema of connective tissue was a prominent feature but the cellular reaction associated with the abnormal presence of fat in many locations and the deposition of connective tissue was not as striking. The shortest period of observation of the animals was 8 days and on the average these animals were observed longer than were those given antuitrin T. The experience with antuitrin T has shown that the acute phase of the reaction occurred early in the course of administration of mononuclear cells. The presence of moderate numbers of mononuclear cells in the tissue of animals treated for longer periods with the crude thyrotropic preparation may bear witness to a more acute reaction that had preceded.

The tissues of the animals which had received the specific metabolic principle in the amounts indicated were of interest because in most instances they appeared to be unchanged. One animal which had lost some weight because of apparent toxicity of the product had a grade 3 edema in the orbit but this was not found in other tissues, and the animal had not become exophthalmic. In some animals very small amounts of fat were demonstrated in muscle fibers.

COMMENT

This report is specifically concerned with certain changes which were observed in the orbit and in various other regions and organs of guinea pigs and which ensued on the administration of antuitrin T for varying periods. In addition, it

includes brief reference to results obtained in comparable animals on the administration of certain other preparations including the solvent for antuitrin T a crude, and a so called purified thyrotropic preparation the potencies of which had been assayed in terms of units not comparable to those of antuitrin T. Since antuitrin T was assayed on the basis of one type of unit and the crude and purified preparations were assayed on the basis of another type of unit, it is not possible to compare the effectiveness of these preparations with that of antuitrin T on the basis of unit potency. It is however, possible to relate the exophthalmos to the tissue changes in any one animal or in any group of animals, irrespective of the preparation which produced the changes.

As hitherto shown (21) antuitrin T produced marked exophthalmos. The crude thyrotropic preparation in the amounts administered was less effective and the purified thyrotropic preparation in the amounts given was least effective of all in producing exophthalmos. The degree of cellular reaction the edema and the connective tissue changes which occurred in these three groups of animals were most marked in those receiving antuitrin T less so in those receiving the crude preparation and least so in those receiving the so called purified product.

This study has shown that a general systemic alteration in fat depots occurred in animals which received antuitrin T. These depots were rapidly depleted of their fat contents, which were replaced by a more translucent gelatinous material. These changes were associated with the infiltration of large numbers of polymorphonuclear leucocytes and tissue macrophages which were loaded with tiny fat droplets. The impression was gained that these large macrophages had phagocytosed fat and were transforming into fibroblasts still containing fat, and ultimately gave rise to connective tissue fibers. Much edema was associated with this reaction. Further evidence of the changes in the fat of the body was shown by the appearance of large amounts of fat in the liver kidney and skeletal and cardiac muscle and in the epithelium of bronchus, ureter, and the ileum.

It is probably of considerable clinical interest that a relationship was recognized between the appearance of fat in the skeletal muscles and profound myasthenia that developed in animals shortly after antuitrin T was given. These cellular reactions as well as exophthalmos occurred in animals regardless of the presence or absence of the thyroid or the testes in the animals in which there was the appearance of fat in abnormal quantities in the foregoing organs.

droplets of fat were also observed in the reticulo-endothelial cells of the lungs, lymph nodes, and spleen. It would seem that the appearance of fat in these specialized cells constitutes a part of the same generalized systemic reaction throughout the body. The results of these experiments suggest that there is a generalized alteration of fat metabolism and that the connective tissue reaction and the exophthalmos may be associated with it.

These observations confirm the opinion of Smelser (45) that tissue reactions may occur in other locations than the orbit. The degeneration of skeletal muscle fibers, illustrated with the hematoxylin and eosin preparations described by Paulson (37) was apparently due to the presence of fat in these muscle fibers. Whether the lymphocytes and macrophages in muscle described by him as well as others are present to remove the fat or to carry away products of cellular degeneration is unknown.

The demonstration of these cytologic changes in tissues, resulting in the ultimate deposition of connective tissue in the involved regions, supports the opinion of Friedgood (24, 26) and Alrd (1, 2) that exophthalmos, after being maintained for a period, becomes irreversible. This also supports the observation of Smelser (47) that there is an increase of the residue which remains after the extraction of water and fat from orbital tissues of animals treated with thyrotropic hormone.

It is well known that pituitary extracts cause an increase of liver fat (3, 7, 10, 30). Barrett, Best, and Ridout (5) showed by labeling fat molecules that fat was transferred from the various depots to the liver. But the possible relation of this observation on the liver to conditions which induce exophthalmos has not been suggested.

Several terms have been given to unisolated substances in the anterior pituitary which influence the mobilization of fat, but their chemical relationship or similarity to the substances which stimulate the thyroid gland is uncertain.

The fact that fasted animals show some of these tissue changes, especially those relating to fat metabolism, confuses somewhat an interpretation of the mechanism of such reactions to antuitrin T. The changes produced by the hormone are not identical with those induced by fasting. Furthermore, they are far more extreme than those seen in the fat depots of fasting animals. It has been pointed out (31) that thyrotropic hormone had toxic effects on animals even before the thyroid response was fully elicited. It is known that animals, when given thyrotropic hormone do not withstand surgical procedures

well (14). In a similar manner fasting animals (49) or animals recovering from surgical procedures (21) do not well withstand the administration of thyrotropic hormone.

The observations of increased fat in the epithelium and lacteals of the small bowel of these animals receiving antuitrin T may have some relation to the observation of Rony and his associates, who found an increase of fat in the lacteals of fasted animals. In a similar way the observation by Binet and his associates of fat globules in the bronchial epithelium and round cells of the lung in fasting animals is recalled by these observations, which show the presence of fat in the bronchial epithelium of animals receiving thyrotropic hormone.

It is quite possible that there may be some relationship between the myasthenia produced in these animals and the myasthenia in exophthalmic goiter. Plummer and Winkler found a positive correlation between the loss of quadriceps strength and the exophthalmos in exophthalmic goiter. These systemic changes may in some way be related to the exophthalmos and to the myasthenia produced in animals by administration of antuitrin T.

SUMMARY

Tissues of animals which during life had been given various thyrotropic hormone preparations and on which very accurate records of the development of exophthalmos had been made were studied grossly and by several histologic techniques.

Antuitrin T which produced the most striking exophthalmos was found to produce gross and microscopic changes in connective tissue not only in the orbit but elsewhere in the body.

The study showed that as a result of the administration of thyrotropic hormone there was a generalized alteration in fat depots, which are rapidly depleted of their fat contents and are replaced by a more translucent gelatinous material. Histologically these changes in fat and connective tissue are characterized by the presence of edema and the infiltration of large numbers of polymorphonuclear leucocytes, lymphocytes, and tissue macrophages. Early in the reaction the polymorphonuclear leucocytes and tissue macrophages are loaded with tiny droplets of fat. Later an increase of new connective tissue is evident. This reaction was correlated with the exophthalmos which had previously developed in these animals.

Skeletal and cardiac muscle fibers during the early period of administration of thyrotropic

DOBYNS STUDIES ON EXOPHTHALMOS FROM THYROTROPIC

hormone lost their striations and were found to contain multitudes of tiny fat droplets which lined up in a pattern representing the cross-striations of the fibers. New cellular elements were present among muscle fibers. Considerable significance was attributed to a close correlation between the presence of fat in the muscles and the myasthenia present in these animals before death a fact which may have clinical correlations.

Further evidence of alterations in fat during the early administration of thyrotropic hormone is the presence of large amounts of fat in the liver kidneys and epithelium from several locations, as well as large phagocytic cells of the lungs spleen and lymph nodes.

These changes took place regardless of the presence or absence of the thyroid.

Since the completion of this investigation there has appeared in the literature a study by Pochin on exophthalmos in guinea pigs, some of which is confirmatory and some contradictory of the results of the present study. Pochin, E. E. Exophthalmos in guinea pigs injected with pituitary extracts. Clin. Sc., 1944, 5: 75-91.

THE USE OF COMPRESSION IN THE TREATMENT OF INJURIES

THE use of compression to arrest and prevent escape of blood and serum into body tissues represents a surgical principle which, to use Homans words, has been "perennially discovered, discredited, forgotten, rediscovered and reaffirmed."

The subcutaneous rupture of blood vessels and the rapid escape of blood and serum into soft tissues are of frequent and everyday occurrence. The blow over the eye or forehead, the crushing of a finger tip, the twist of an ankle—all lead to rapidly forming swelling and the subsequent discoloration that indicates that the blood vessels have been torn and blood has infiltrated the surrounding tissues. Severe contusions and crushing injuries of soft tissue and bone are followed by the same train of events in a more exaggerated form.

When one is confronted with an open wound from which active bleeding is taking

place one's first instinct—whether layman or surgeon—is to apply pressure to stop the bleeding. The surgeon in the operating room almost daily instinctively and logically presses gauze sponges or "laparotomy pads" against a bleeding surface to arrest oozing. The same principle can be employed, and with almost equal effectiveness in the control of bleeding which does not meet the eye as a rapidly welling pool of blood but which is accumulating under the surface in direct ratio to the extent of injury and the elasticity of the overlying tissues.

When one recalls what happens when a considerable quantity of blood infiltrates soft tissues—the harmful compression of fragile living cells, the slow disintegration of red cells, the fibrosis that follows the absorption of serum and disintegrated corpuscles—it becomes a matter both of logical treatment and of importance to arrest such bleeding as promptly as possible. When one recalls further that after an extensive crushing injury the loss of blood into the soft tissues can be so great as to lead to shock and threaten life, the arrest of such hemorrhage becomes a matter of life and death. The most certain means at our command of controlling such bleeding is by smooth firm compression of the affected area.

There is a second important group of cases in which similar conditions obtain—those in which blood without red cells escapes rapidly into the surrounding tissues and leads to the same local and general symptoms of swelling, distention of tissues and fluid loss. Whatever the cause of the fluid loss that rapidly follows exposure to extremes of heat and cold—in increased permeability of damaged capillaries,

local vasodilator reaction which causes the region (surrounding a burn) to become an open shunt with capacity to contain a maximal amount of intravascular blood¹ or whether still other factors at work—every worker interested in the treatment of burns or of injuries due to freezing has been concerned with the rapid loss of fluid into the tissues and with the serious effect of such loss both on the tissues at the site of injury and on the entire body mechanism. With the concentrated attention that has been given to these injuries in recent years it has become increasingly apparent that the prompt application of pressure over the injured area is the most certain and effective means of preventing and checking fluid loss and of arresting the 'white hemorrhage' which is so important a factor in the clinical picture that develops rapidly after severe injuries due to extreme heat and cold.

A third group of cases in which the use of compression is an important factor in bringing about recovery is well illustrated by a simple case report from Sampson Gamgee's *Surgical Lectures* published in 1883²

On the 18th September 1879 a bloated middle-aged man came before me in the out patient room with his right leg big, tense, purple, and exquisitely tender.

"The man had earned his living as a hawker and had been a hard drinker. On admission the right leg was of greatly increased size, and of deep purple colour, the skin tense and shining and intensely sensitive to the slightest touch. Circular measurement of the two legs gave the following result:

	Right	Left
At the middle of the patella	18½ inches	17 inches
Six inches below	18 inches	7 inches
Round the malleoli	14 inches	1 ¾ inches

Placing the man on his back and raising the foot I enveloped the limb in a layer of cotton wool, over which I constructed a compressing millboard and banded with laticework.

"September 19th, 9 a.m.—After the lapse of 13 hours bandages very loose from the considerable

subsidence of swelling which has taken place in the twelve hours since they were applied. I applied another bandage with firmer pressure and suspended the limb. The patient had passed a comfortable night, with the exception of some pain between midnight and 5 a.m. He is now perfectly comfortable.

8 15 p.m.—Has been very easy all day. On removing the apparatus the limb is much paler and softer and scarcely tender on pressure. The patient's spontaneous expression is 'It is wonderful how I can bear it handled now and I could not stand a feather touching it last night. The following are the circular measurements of the right leg:

		Decrease in 24 hours
Mid patella	17 inches	1 ¾ inches
Six inches below	15 ¾ inches	1 ¾ inches
Round the malleoli	13 inches	1 inch

The strips of pasteboard were now re-moistened, to fit the shrunken limb and banded to it, lattice-work fashion, over cotton wool with increased pressure. The application last night though conducted most gently caused occasional exclamations of intense suffering but the patient bore it tonight, though executed comparatively roughly without the least pain. The same process was repeated daily to follow up the decreasing limb with equable pressure and at the end of a week, the two legs were of equal size.

Admitting the beneficial influence of the horizontal position of the body and of the suspension of the limb in the flexed position, there can be no question that the immediate relief of pain and the rapid subsidence of swelling were chiefly due to smooth elastic pressure."

Gamgee cites a number of similar cases in which disabilities resulting from widespread exudation through the soft tissues associated with a chronic inflammatory process responded rapidly to the application of compression and immobilizing splints. Further more he points out that many English, French, and German writers during the century preceding had repeatedly emphasized the importance of compression in the treatment of injuries and of chronic inflammation—a method "forgotten rediscovered and reaffirmed. Ironically perhaps, Gamgee obtained such good results by adhering to sound surgical principles that he was reluctant to accept the teachings of his friend and classmate Lister.

It seems almost superfluous to repeat in a surgical journal Blair's emphasis on "The

EDITORIAL

Influence of Mechanical Pressure on Wound Healing' : but a few lines deserve repetition because so much of good surgical sense is compressed in them

There are chiefly four basic things to be gained by the use of properly applied mechanical pressure to wounds

"The elimination of dead spaces.

"The control of oozing.

"The limitation of venous and lymph stasis.

Blair V. P. The influence of mechanical pressure on wound healing. Illinois M. J. 924, 46 249-25

Limitation of the amount of plastic material that pours into the wound."

Fowler of the University of Minnesota said at a recent meeting in Minneapolis that an understanding and appreciation of the value of compression was one of the outstanding lessons learned during the war. Perhaps it has been so well learned that it will not again have to be rediscovered and reaffirmed

Committee on Arrangements
HOWARD PATTERSON *Chairman*, FRANK GLENN *Secretary*

PLANS DEVELOP FOR 1946 CLINICAL CONGRESS OF THE AMERICAN COLLEGE OF SURGEONS

THE announcement in the March issue of SURGERY, GYNECOLOGY AND OBSTETRICS of the definite plans for holding the 1946 Clinical Congress of the American College of Surgeons at the Waldorf Astoria in New York City from September 9 to 13 has been greeted with enthusiasm. A large meeting and exception ally keen interest are assured. The four years without a Clinical Congress have been years impressively lacking in a focal point for intensive study of trends in surgery, and surgeons everywhere are eagerly anticipating the resumption of the annual meeting.

Progress does not stop when there is no Congress, of course, but the application of new techniques and ideas is delayed when there are no opportunities for the meeting of minds that a large international conference affords. The Clinical Congress makes a convenient annual milepost by which to calculate and to evaluate advances in surgery and it provides a spur to progress through this function and through its inspirational influence.

Surgeons need the stimulation that comes from directly hearing of new developments from the lips of those who helped to initiate them. They need opportunities to ask questions, to participate in discussions, and to observe other surgeons at work, both in the local hospitals and on the motion picture screen. The latter teaching device in particular is becoming increasingly profitable and popular as more good medical films are produced and at the Clinical Congress ample opportunity is provided for surgeons to view the newest and best pictures.

The Clinical Congress, as the previous article indicated, will be the usual five-day session, embracing forums on fundamental surgical problems

panel discussions, clinical conferences, symposia, demonstrations, films, scientific sessions, hospital conferences, exhibits, and the formal Presidential Meeting and Convocation. This year the Convocation will be a particularly momentous event, since in addition to the initiatives of the current year there will be present a great many of the accumulated total of 2,744 surgeons who were received into fellowship in absentia during the four war years in which no Congress was held. It will also be an occasion of reunion for the Fellows, both new and old, many of whom have been overseas on military duty much of the time since the Boston Congress in 1941.

The new officers of the College who will be installed at the Presidential Meeting and Convocation are Dr. Irvin Abell of Louisville, as President; Dr. Leland S. McKitterick of Boston, as First Vice President; and Dr. F. Phinley Calhoun of Atlanta as Second Vice President. The Presidential Address will be given by Dr. W. Edward Gallie of Toronto, the retiring president.

Plans are progressing for making the programs of all of the scientific sessions, morning, afternoon, and evening, provide the most comprehensive delineation possible of advances in surgery and related sciences during the five years since the 1941 Congress. The various surgical specialties, ophthalmology, otorhinolaryngology, neurology, orthopedics, obstetrics, gynecology, urology, plastic surgery, and the others, will be covered specifically and also as they are related to general surgery. The four-day hospital conference will be devoted to all phases of transition, period plans and problems. A detailed outline of the programs will be published in the next issue.

Advance registration and hotel reservations are urged upon all who plan to attend the Congress.

PENETRATING CRANIAL WOUNDS A SUMMARY OF METHODS USED IN MANAGEMENT

Collective Review

J. E. WEBSTER, M.D. and E. S. GURDJIAN, M.D. F.A.C.S. Detroit, Michigan

INTRODUCTION

RECENT literature pertaining to the management of cranial wounds in World War II has added important new information to the older concepts of treatment. The reports which are continually reaching publication serve to advance our knowledge and unify opinion. Any general review of this subject must consider the present incompleteness of information. We propose merely to summarize the experiences of various observers to date in the interest of consolidating reports and to emphasize the application of the measures employed in war surgery to related civilian injuries.

This summary is devoted mainly to a consideration of penetrating wounds caused by bullet or shell fragment missiles (Fig. 1). Injuries of this class produced by forces peculiar to high velocity represent a unique neurosurgical problem. Penetrating types of civilian cranial injuries of low velocity present quite different requirements in care. The difference in the degree of destruction of scalp, skull and cerebral tissue dictates the differing principles in surgical management. The radical measures employed in the débridement of high velocity wounds are not required in the less destructive, low velocity civilian injuries (hammer, blackjack, rocks, knives, car door handles, electric fan blades, stationary objects). This distinction is made at the outset since only brief consideration is given to the usual low velocity type of penetrating wound as encountered in civilian practice.

The survey includes observations made in 300 patients with cranial wounds produced by missiles of high velocity and treated in the 36th General Hospital which was located in Italy and in France. Because of the hospital's location all types of wounds were observed including one group of 40 cases of late wound débridement in German prisoners of war (210, 211, 212). The civilian patients with gunshot injuries of the brain were treated at the Detroit Receiving Hospital and Grace Hospital during a period of 20 years.

Before the principles followed in the care of patients with cranial wounds in World War II are described a brief review is made of the history of the care of war wounds in general and of those historical factors and opinions marking progress in the care of cranial injuries. The time periods are divided for consideration as follows: Early World War I, Interim and World War II periods. The neurosurgical methods and technique employed in World War I are reviewed in some detail for comparative purposes. Brief consideration is given to the applicable physics of tissue destruction produced by high velocity injuries. A group of nonmilitary gunshot wounds of the brain was included in order to evaluate methods of treatment used in civilian practice.

HISTORICAL

EARLY PERIOD

It has been reported that the first use of gun powder by the English was in the Battle of Crecy in 1346 (100). The poisonous nature of the wounds so produced was described by Giovanni da Vigo (1460-1525), surgeon to Pope Julius II.

From the Department of Surgery, Wayne Medical College of Medicine and the Department of Neurosurgery, The Detroit Receiving and Grace Hospitals, Detroit.

INTERNATIONAL ABSTRACT OF SURGERY

who stated that all gunshot wounds are not only contused and burned (requiring moist applications) but also poisoned by the powder (requiring dessiccation), and hence difficult to cure" (120) "He advised cauterizing the wounds by means of boiling elder oil or actual cautery." Brauns Weig a surgeon of Strasbourg, and others agreed with this plan during the 15th century (80) A new era was thus begun in warfare attended with "superstitious terror" aroused by the use of the new weapons which produced remarkable noise and flame upon discharge and profound acute and late effects upon human tissue. In the attempt to reach the openings of entrance and exit and track of the ball were incised the wound dilated by tents or other means terebinthins or boiling oil poured into it irritating compounds and ointments applied and it was only after the wound was considered to be fully purged of its venom and foul humors by the extensive suppurative action thus kept up that cicatrization was permitted to be established" (95)

The 16th century marked the beginning of a revolutionizing treatment of war wounds in general. Alphonse Stenzen surgeon to Paul III from 1534 to 1549, in the early part of his career held the same views as Weig and Vigo as to the poisonous nature of gunshot wounds. He made important improvements in wound management, advising upon the search for balls, their extraction, and upon the subject of dressings (80) Later in this era Ambrose Paré (144) leading surgeon of the Renaissance and founder of military surgery as a science and art, merely continued the early practices, merely dressing wounds after applying a digestive (31) Maggi of Italy supported the doctrines of Paré, which were published in a treatise on gunshot wounds (80) Leone Botall, and Fallopius "at once embraced the views of these eminent masters and the employment of too complicated instruments for the extraction of balls deprecated trephining for depressed gunshot fractures of the skull advised the discontinuance of the application of fatty substances to gunshot wounds and insisted upon the antiphlogistic treatment (50) In this century Botallus (17) described foreign bodies in the brain Complicating cerebral abscess was recognized but was not drained even though it was recognized that death would result by expectant treatment Opinion was confused as to the wisdom of removing bone fragments from fractured skulls it was "believed wise to bore if fissure in the skull was present. Dyes were used

to detect the discontinuities of the skull, a practice employed in the hippocratic era (13) A "Treatise on Gunshot Wounds" by Thomas Gale appeared in 1563 and was the first English publication on military surgery This was followed in 1613 by the "Chirurgeon's Mate" by John Woodall in 1667 by the "Eight Chirurgical Treatises of Richard Wiseman" one of which was devoted to gunshot wounds, and in 1678 by the "Treatise on Gunshot Wounds" by John Brown (80) In the 17th century, agreement was reached about the value of opening the skull for the drainage of purulent collections and for subdural hematoma (125)

During the latter part of the 18th century (1792), Percy (149) in the *Manuel du Chirurgien d'Armée* wrote "The first indication of cure is to change the nature of the wound (gunshot) as nearly as possible into an incised one." This treatment by incision a return to older practices, was widely used, particularly by the French, the reason for its use being that "it was necessary to obviate tension and prevent strangulation of neighboring tissue by tumefaction caused by inflammation arising in the track of the projectile (95) The term "débridement" was used to describe this method of wound management. English surgeons opposed the French practice following the advice of John Hunter who recommended a simpler and more rational treatment in an outstanding treatise published in 1794 and entitled, "Blood, Inflammation and Gunshot Wounds." Incision of the wound was advocated only "when something can be done for the relief of the patient by the opening (securing a wounded artery) or the future good arising from it (106)

Heister (90 128) referring to cranial wounds in the 18th century made the following observation "Gunshot wounds which affect the cranium are for the most part attended with great danger For even those which appear very slight externally frequently bring on terrible symptoms by the concussion of the internal parts which they shattered, or the internal laminae of the cranium are case the extravasated blood has no vent, nor can splinters of the cranium be extracted. Death therefore must be the issue unless prevented by the trepan

The Napoleonic Wars which ended in 1815 marked new progress in the care of gunshot wounds of all types. Mr Guthrie (81) quoted Sir Astley Cooper as stating that in the Peninsula War between 1808-1815 "the art of surgery received from the practical experience of that war an impulse and improvement unknown to it before.

Baron Larry (117) in his memoirs of the Napoleonic campaign in Russia. Germany and France clearly stated the principles which he followed in the treatment of cranial wounds. He reported that in a wound of the head accompanied by a fracture of the cranium should the fragments of bone be displaced and driven internally so as to injure the brain and dura mater the trephine is indispensable. When the foreign body which has caused the wound is enclosed between the pieces of bone or has penetrated into the interior of the cranium—the case is again one which demands the application of the trephine. Finally, when the surgeon is assured of the existence of effused fluid under the cranium, this instrument is also indicated. He believed that the operation should be performed as early as possible recognizing that 'inflammation is generally established in the meninges after the first twenty four hours succeeding the occurrence of the injury. Guthrie (84) held similar views, subscribing to operative treatment based upon observations made in the Peninsular War. After suggesting that a cranial wound be examined with a blunt, flat probe to determine the extent of damage, he raised the question 'What is to be done when depression and breaking down of the inner table have been ascertained? There can be no hesitation—that in all such cases the trephine should be applied although no symptoms should exist, with a view to anticipating them. The old doctrine, it may be said in regard to fractures generally is revived in these cases but on a principle with which our predecessors were not sufficiently acquainted. A patient very often survives a mere depression of the skull he may and occasionally does, survive a greater depression of the inner than of the outer table but it has not been shown that he ever does survive and remain in tolerable health after a depression with fracture of the inner table when portions of it have been driven into the dura mater. The result of my experience has rendered it imperative to remove at once all portions of bone or foreign substances which have materially injured the dura mater although no symptoms of compression should be observed. Hennen (92) emphasized the importance of trephine for compression without fracture. 'Where there is no wound the case becomes dubious and we are reduced to act upon probability founded upon gestures of the patient, his sensibility to pain upon pressing on a particular spot, or we may be guided by what the French surgeons place much dependence on viz. the existence of paralysis, which is most commonly on the side of the body opposite to the compressed portion of the brain

Fig. 1. Examples of penetrating missiles removed from the brain. Tiny bone chips and particles of clothing are present on the surfaces of the shell fragments.

The military operations in Algeria (1846) in Schleswig Holstein (1849) and in the Crimean War (1854-56) presented opportunities to test again the applicability to military practice of the great improvements accomplished in the civil practice of surgery in Europe since the termination of the war in 1815. The practice generally, of 'what has been styled conservative surgery' characterized the interlude between wars (95).

The trend toward conservatism in cranial surgery as well as in general surgery was demonstrated by the views expressed and by statistics which began making their first appearance. Longmore (95) pointed out that a gunshot wound of the head had previously been an indication in itself for the use of the trephine, that earlier in the 19th century trephine was used for injuries with out fracture. Such preventive trephine has been proved to be useless as well as dangerous and is universally acknowledged not to be an admissible operation. He stated that the majority of the English surgeons after the Peninsular War limited the use of trephine to fractures with depression causing interruption of cerebral function, fractures with bone indriven into the cerebral tissue and where an abscess had developed and was capable of evacuation. The trend was to confine the practice of trephine 'within still narrower limits. Stromeyer (95) an experienced German surgeon reported 41 gunshot fractures of the skull with depression. Of the 41 cases, 7 terminated fatally. Of the 34 patients who lived, only 1 was trephined and this was the only case of trephining which gave a favorable result in all three campaigns (Schleswig Holstein 1849). Stromeyer had earlier advocated trephine but stated in his *Principles of Military Surgery*

INTERNATIONAL ABSTRACT OF SURGERY

that he had abandoned the practice (183) Macleod (122) in *Notes on Surgery of the War in the Crimea* reported that 67 patients with penetrating wounds of the skull had all died. In the treatment of 851 cranial wounds the trephine was employed only 28 times and 24 of the patients died. Thus the modest success of trepanation, based upon the results in two wars, resulted in endorsement of the modern treatment of expectancy and the avoidance of operation except in rare cases (122).

Macleod reported that the teaching of all was to lead us to wait to purge the patient thoroughly to remove only such pieces of bone as could be got at with the forceps and which were quite detached and loose to bleed, if need be, locally and even generally to use cold applications when there was a fear of inflammation to enjoin perfect rest, not only to the body generally but, if possible, to the special senses also by isolating the patient and thus removing the stimuli to their exercise to enforce the lowest diet and to continue all this treatment for a long period even after all danger seemed past and finally to treat any incidental complications on general principles.

This extract is not only expressive of the opinions of a single individual but may be regarded as embracing the views of the majority of surgeons of this period (80).

Information resulting from the War of the Rebellion in the United States (126) raised some doubt as to the reasonableness of the conservative conclusions formed by the continental surgeons. Reports showed that successes attended surgical intervention in cranial wounds. Gross (80) published a comparison of the results of trephining compared with those of the expectant plan of treatment. Of 160 patients on whom the trephine was employed 60 per cent died and of 573 with serious conditions treated by expectancy 74 per cent died. Of 126 cases in which fragments of bone were elevated or extracted, or foreign bodies were removed 55 per cent were fatal. "After all operations of every kind the rate of recovery was 41 per cent. By the conservative or expectant plan only 25 per cent lived, making in favor of operative interference 16 per cent of recoveries." Gross (80) reviewed the plan of treatment of cranial wounds proposed by Neudorfer (137) who was so prejudiced against the trephine that he not only did not use it himself but advised that it be excluded from the armamentarium of the army surgeon. He summarized the views of Stromeyer (183) Pirogoff (155) Legouest (119) Williamson (217) Demme (51) and Matthew (125) in show-

ing the confusion of opinion. He pointed out that the trephine is employed by surgeons of known experience and high reputation for widely different lesions and symptoms—that with one, its results have been invariably fatal and is positively contraindicated under all circumstances. With another the results have been so favorable that its application is not restricted to a limited number of lesions (Pirogoff, Legouest, Williamson). The variance in the experience between the American surgeons and those abroad was ascribed by Longmore (95) to the fact that "the former did not restrict the application of the trephine to otherwise hopeless cases and to the difference in the effect of the old round ball and the sharp minie bullet.

Toward the end of the 19th century advanced opinion formulated the following policy in the management of cranial wounds "When irregular edges, points or pieces of bone or foreign substances are forced down and evidently penetrate—not merely press upon—the cerebral surface or where abscess manifestly exists in any known site and relief cannot be afforded by simpler means at the wound itself trephining is the proper operation but in all other cases harm will probably be avoided by abstaining from trephining while benefit will be effected by simply resorting to long-continued constitutional treatment (95). It was recommended that if operation was necessary "the earlier that it is done the better."

Three years following the War of the Rebellion (1867) Lister's principles of antiseptic were enunciated, although in the Franco-German Wars, wounds of all types continued to be treated by unclean methods. Injuries up to this period were caused mainly by muzzle loading rifles and large caliber balls, although in the latter part of the Crimean War muskets were being transformed into *armes de précision* with rifled barrels and smaller balls. There were few wounds produced by artillery fire (127).

The magazine breech loader was introduced in 1892 and the use of this weapon greatly influenced the type of wound produced and the resultant requirements in wound care. Used during the Spanish American (1898) and the South African Wars (1899-01) this type of rifle fired a conoidal type of missile which resulted in a minimal degree of track damage (127). Wounds thus produced were effectively treated by means of a simple dressing and the results were satisfactory since in general, primary wound healing occurred (134). Since (176) Chief Surgeon in the Spanish Amer-

Extracted from Holmes, *System of Surgery* Philadelphia; Henry C. Lea's Sons, 1881.

can War reported that conservative surgery is the pride of the modern doctor on the field of battle. The stacks of amputated limbs that constituted such a gruesome and constant sight after every battle during the Civil War will never be seen again on the field of battle where modern surgery is practiced. The first aid dressing properly applied at the right time constitutes in the vast majority of cases, almost sure protection against infection of the wound. Prophylaxis has largely taken the place of operative surgery in the field. Our recent experience has demonstrated that the small-caliber rifle is the most humane weapon. If the wounded survive the immediate effects of the injury the prospects of recovery are good. What a contrast with the experience of the surgeons during the Civil War only thirty five years ago. At this point artillery was still little used and high explosive bombs and land mines were unborn instruments of destruction. Records of the period indicated that shell fragment wounds were invariably infected.

Prior to World War I, von Bergmann (203), Pappillon (143) and Doyot (55) recommended operative treatment for penetrating cranial wounds, employing an open method. Zoeger Von Manteuffel (205) in 1906 reported upon the

inadequacy of the conservative management when used in the Russo-Japanese War (1904-5). In the open treatment, after débridement of the comminuted bone, neither the dura nor scalp was closed which usually resulted in herniation of the brain and frequently the death of the patient. When this treatment was used in the Bulgarian Turkish War (1912-13) by Colmers (39) 70 per cent of all tangential gunshot wounds of the head with injury of the brain died of infection.

WORLD WAR I—GENERAL CONSIDERATIONS

Surgeons in World War I were unprepared to treat the type of wounds which they encountered because of two major changes in the instruments for wounding. The first was the increased velocity of missiles and the second was the frequent use of artillery fire in place of rifle injury to the extent that the ratio of gunshot wounds to those produced by artillery fire was reversed (18).

The concept at this period of a conservative management of war wounds of all types even with the knowledge of asepsis proved to be a failure. Established methods resulted in a high incidence of morbidity and mortality due to infection (66-189). Since antisepsis were in vogue, early use was made of various solutions to cleanse the

A policy of early operation débriment, and complete closure of the cranial wound was recommended by Barany (11 12 13) Willems (216) and Cushing (44) being first suggested in 1913 by Clairmont (36) and Colmers (39) Barany (11) particularly grasped the importance of the removal of devitalized tissue and closure of the dura and scalp without drainage. Cushing (44 127) announced a surgical policy in dealing with this type of wound in 1918 advising a catheter suction method of débriment. Ultimately this technique became a standardized procedure. In view of this fact, a detailed description is presented of the "Directions to Neurosurgical Teams" as outlined by Cushing (127)

It was first recommended that every scalp wound be considered as a potential penetrating wound of the skull and brain, a principle founded upon the observation of Hippocrates *Nullum capitis vulnus contemnendum*. As a part of the general attitude toward all wounds, an all or nothing plan of débriment was recommended. The observation was made that patients with penetrating wounds of the brain were able to tolerate transportation rather well before operation but poorly during the first few days after operation. It was held that craniocerebral cases "in more or less shock need not undergo a period of resuscitation. Local anesthesia combined with morphine was suggested as the most suitable anesthesia (49). The directions stated that the chief source of the high mortality in cranial wounds was infection—infection of the meninges direct infection of the brain leading to encephalitis, and infection of the ventricles."

The principle recommended in the operative technique was the removal of the contaminated wound margins and of all foreign material from the brain along with devitalized brain tissue. The "tripod" incision was advised to provide exposure of the underlying bone defect. The directions stated only in the case of large scalp defects is the switching of flaps necessary for closure, and it is questionable whether this is desirable. The technique suggested for the exposure of the brain track was the use of three or four perforations about the skull defect and the tilting up and removal of the bone "en bloc." It was advised to leave as small a bone defect as possible—a quarter of an inch margin beyond the defect suffices. The area of dural laceration should not be enlarged. The débriment of the contused brain and track can best be carried out with production of the least damage to the brain by gentle suction and irrigation with a soft rubber catheter. The catheter detects indriven bone fragments as well

as does the finger and then these can be picked out with delicate forceps. Metallic fragments of small size are surprisingly well tolerated. No mention is made in the technique outlined concerning the closure of the dura. Horrax (102) and Rand (158) have stated that it was usually not closed since, as the latter reported, the incidence of sepsis where the dura was closed was disproportionately high." Use was also made of dichloramine T in oil as an antiseptic "particularly suitable for infections in the central nervous system tissues."

Cranioerebral wounds were classified into 9 special groups based principally upon the type of damage produced. These groups and their percentage of mortality were as follows (127) (45)

- 1 Wounds of the scalp (about 5%)
- 2 Cranial fractures without dural penetration (10%)
- 3 Cranial fractures with depression and dural penetration but without extrusion of brain (20%)
- 4 Wounds usually of gutter type with brain extruding and indriven bone fragments (30%)
- 5 Wounds usually of penetrating type with indriven bone fragments plus metal (40%)
- 6 Wounds types 3 and 4 with penetration of bone and metal opening the ventricles (50%)
- 7 Craniofacial wounds or orbitofrontal or temporo-petrous wounds in which the ethmoid or petrous sinuses are open (60%)
- 8 Perforating or traversing wounds (70%)
- 9 Extensive bursting fractures with fatality usually due to trauma rather than infection (100%)

Harvey (88) recommended that every case in Group 2 should be explored and trephined that if the pathway from the external wound to the fracture is continuous then infection will, in many cases,—even with the simple depressed fracture without dural penetration—lead to meningitis or an abscess in a contused adjacent cortex. The statement was made in Harvey's report that patients in whom the dura was closed did "badly." As a general policy it was advised to allow the dura to remain open and in addition to drain the scalp with a small rubber wick to prevent damming back of the infection which would lead to meningitis or a cortical abscess. It was noted that in the gutter type of wound classified as Type 4 the probability of infection was of the greatest degree and it was held that wounds in which infection of the scalp or its intra cranial contents is problematical should be left open for free drainage. Penetration of the ventricle was found to result in a high mortality. (Cushing noted no recoveries in patients in which the ventricle was penetrated by a metallic pro-

jectile.) The management of wounds involving the orbit consisted of enucleation of the destroyed eye, and removal of the indriven bone fragments from the bony orbit and the pulped brain from the track. Bilateral decompressions were sometimes performed on extensive bursting fractures, but recovery was unusual.

The mortality rate including the results in all types of wounds with dural penetration was 37.5 per cent, being reduced from 54.5 per cent in the first group of patients to 28.8 per cent in the last group (44).

BRAIN ABSCESS, FUNGUS, AND MENINGITIS— WORLD WAR I

The report by the Surgeon General (127) summarizing the complications observed following penetrating wounds of the brain stated that the "principal cause of death in patients with head wounds after return from overseas was abscess of the brain. The abscesses frequently occurred in cases in which there were retained foreign bodies. In 219 cases Cushing encountered 8 instances of brain abscess within a few weeks of injury (24). In 37 cases studied by Sargent and Holmes (169, 170) the overwhelming frequency of brain abscesses in the first three to six months after injury was shown. 28 patients developed abscesses in that period, whereas the complication appeared in a 6 to 9 month interval in an additional 7 cases. The latest appearance of brain abscess was in the eighteenth month. The history of World War I recorded that multiple abscesses were found to be practically always fatal, and recovery from a brain abscess without a capsule was extremely rare (127). It was stated that the primary stage of abscess formation was one of septic encephalitis for which surgical procedures would give no relief. The ideal time for operation was after the formation of the capsule.

It is sometimes difficult to determine just how drainage of pus should be accomplished or whether simple aspiration with a needle should be made" (127). The procedures used for the drainage of abscesses varied in magnitude from the use of an osteoplastic flap to that of a simple trephine opening. It was noted that the best results in the treatment of this complication were obtained in the drainage of single abscesses with capsules. A second opinion stated that "consideration of all the facts justifies the conclusion that the most favorable time for accurately placing a drainage tube in an abscessed cavity is when the pus is first discovered. It is often possible to empty the abscess completely at this time, and there may be very little subsequent discharge. The drainage tube

should be fixed to the scalp and should not be removed until drainage has discontinued" (127). Brain abscess unrelieved by operation was considered to be fatal yet the vast majority of patients (97.5% in Sargent and Holmes series) died after the drainage of pus (138).

Fungus was observed to be one of the most frequent complications following the drainage of cerebral abscess, and the mortality was high. A fungus was the "result of an undrained abscess with or without hydrocephalus or an encephalitis." The notation was made that the treatment of the condition of fungus is as a rule unsatisfactory. It was held important that any associated accumulation of pus should be drained (127).

RETAINED FOREIGN BODIES—WORLD WAR I

Prior to World War I, a conservative attitude was taken toward the removal of foreign bodies within the cranial cavity as pointed out by Pilcher (152) in an excellent review of this subject. Sir Benjamin Brody in 1828 (20) approved of this policy. Later however cases were reported in which the foreign bodies within the brain substance were removed. In the Medical and Surgical History of the War of the Rebellion (126) 85 cases of bullet removal were reported. Andrews (4) in 1868 and Wharton (214), 10 years later advocated the removal of retained bullets when they were localizable and accessible. Morris (133) in 1887, Papallion (143) in 1894, and Hewitt and Lidell (93) in 1887 held this same view. Phelps (150) in 1906 stated, "There is probably no authenticated case in which the bullet left in the brain substance has failed to work mischief. DaCosta (46) in 1910, wrote "that practically every lodged bullet (in the brain) constitutes a fatal condition and it should be removed if possible, even if there are no symptoms."

Following the use of roentgen rays in visualizing and localizing intracranial foreign bodies, first suggested in 1896 by Stubenbord (152, 184) removal became a more practical procedure, and was more widely practiced. (Rouviellois [163], Cazamian [34], Regard [159] and Villandre [200] recommended removal of all foreign bodies.) As a result it was observed that a relatively small number of retained foreign bodies were discovered in patients with head injuries following their return to the United States after World War I (127). In two series aggregating 392 patients with head injuries at general hospitals, 29 had intracranial foreign bodies which were either pieces of metal or bone fragments. Frazier and Ingham (63) reported our percentage of retained foreign

bodies which is 10% is almost identical with that recorded by Sargent and Holmes 164 in 1567 cases, or 11%. Of a series of 9 patients with retained missiles treated by Bagley (9) 7 were operated upon. Four had an associated abscess with a positive culture. In 3 cases there appeared to be no signs of brain disturbances from the foreign bodies and in these the cultures were negative.

Frazier's (127) indications for the extraction of foreign bodies were as follows. Foreign bodies causing encephalitis or epileptic seizures should be extracted. Those apparently latent should be left alone. This opinion was subscribed to by Bagley (9) Demmer (52) Von Eiselsberg (204) and Coleman (38) Wagstaffe (206) noted that the incidence of epilepsy was slightly higher among those with retained foreign bodies.

INTERIM PERIOD BETWEEN WORLD WARS I AND II

Interest in penetrating cranial wounds slackened after reviews were made of war experiences by World War I authors. The final surgical techniques evolved were considered as satisfactory. The possibilities in neurological surgery revealed by the war focused attention upon civilian neurological problems. A rapidly broadening field resulted in the training of a number of general surgeons into neurological surgeons who became experts in this particular speciality and in due course of time trained others.

There was thus available at the start of World War II a considerable number of trained neurosurgeons as well as a rapid means of training additional men through short courses or by preceptorship. In contrast to World War I, this was a major advantage true in all specialties when medicine mobilized for war.

A second advantage at the start of World War II lay in the improvement in transportation and its means of mass production. Slow and inadequate methods formerly used were replaced by streamlined methods employing a greater number of men, units, and vehicles and the air as a medium for transportation. Expeditious evacuation from the point of injury to hospitals for definitive treatment, recommended early by Tonnies (191) was constantly a foremost consideration although it was subject, at times to insurmountable difficulties. This factor was of major importance in the management of cranial wounds (114).

Research during the interval between the wars had resulted in the introduction of sulfonamide drug therapy in 1936 with evidence of astonishing results in the treatment of infection.

Sulfonamide therapy was observed to be particularly efficacious in the treatment of infections caused by the streptococcus of the beta hemolytic type the Lancefield Group A hemolytic organism, the meningococcus pneumococcus and gonococcus Staphylococcal infections, however were not benefited to the same degree. The mode of action of this drug by bacteriostasis permitted the control of infection of the central nervous system following cranial wounds in a high percentage of cases.

A widening knowledge concerning body chemistry fluid balance anoxia blood replacement the treatment of shock and wound healing added significantly to the effectiveness of the surgical treatment.

The pathophysiological conditions of the brain resulting from trauma were more clearly understood. Many contributions to the literature both of an experimental and clinical nature, had been made during the interval between World Wars I and II.

An important contribution pertaining to the improvement of the technique for the débridement of penetrating wounds was made by Horrax (99) in 1940. He suggested that such wounds be treated by more radical excision with coming of the track of devitalized tissue in place of the catheter suction débridement. This suggestion later put into practice in World War II proved to be a significant aid in treatment.

Under these circumstances, neurosurgeons in general faced the cranial wounds produced in World War II, adequately prepared organized and equipped.

MECHANISM OF INJURY FROM BULLET AND OTHER PENETRATING WOUNDS

Wounds from high velocity bullets and shell fragments are relatively recent experiences in military surgery. It is only during the past 60 years that high velocity bullets have come into use, and only since World War I that high velocity shell fragment wounds have been noted with frequency. Whereas a low velocity weapon may traverse the body mainly with injury to the immediate neighborhood of the track, high velocity missiles cause extensive damage also at a distance from the track in the tissues. It is not uncommon to see organs, bones and other tissues severely damaged at some distance from the bullet passage. Usually blood vessels and nerves are more resistant because of their elasticity and thus they may escape anatomic injury. On the other hand, vessel injury may be seen at a distance from the missile track by "splash" of the blood against the

intima with longitudinal tears. Thrombosis, secondary tear with hemorrhage from necrosis, or aneurysms, may ensue.

The agents of injury especially concerned in this study include bullet and shell fragments, as well as certain tools and utensils used in low velocity penetration of the cranial cavity. In most instances, pointed bullets are seen in military injuries, whereas round nosed missiles are found in civil practice. In practically every instance, bullets used in military practice are jacketed with a core of lead in the center. Jacketed bullets usually retain their shape except at impact with bone at velocities of 2,500 feet per second or more. In civilian practice with soft bullets, it is common to see the missile shattered into many fragments at impact. In rifle injury the muzzle velocity of the bullet may be 2,000 feet per second or more, and the rifling causes the bullet to rotate about its long axis approximately 3,000 times per second with a velocity of 500 or more feet per second. Sir Victor Horsley (104) has attributed the explosive effect of high velocity missiles to the rotation of the bullet about its axis rather than to its muzzle velocity. This will be discussed in greater detail in the next few paragraphs in connection with recent experiments pertinent to the problem.

Shell fragments may have extremely high velocities, and it has been estimated that they may travel from 4,000 to 5,000 feet per second near the site of explosion. They vary in size and shape and they are more likely to become contaminated with clothing, hair and helmet lining which may be introduced into the cranial cavity. Whereas bullets usually cause a neat wound of entrance and possibly also a clean wound of exit, shell fragments may cause large, lacerated wounds of entry. In accordance with the velocity irregular tears or bruises of the struck area may be seen. Frequently the fragments remain in the cranial cavity. It is interesting to note that in certain instances tiny fragments may be dispersed within the cranial cavity. Among this group of cases there may be instances of relatively little brain damage.

Low velocity penetrating wounds of the skull and brain may be produced by knife blade, ice pick, glass, umbrella end and many other tools or every day objects. Ordinarily infection is seldom introduced into the cranial cavity and this may be partly explained by the fact that during the period of thrust dirt particles are held back as the object enters the scalp and skull.

A very important difference between high velocity and low velocity injuries is to be found in

the type of damaged brain about the missile track. With high velocity injury there is palpating at long distances, whereas with low velocity bullet wounds and with stab and similar penetrating wounds, there may be no damage except for the track in the tissue. Wilson (218, 219) states that

the wounding effect depends upon, first, the amount of energy transmitted to the tissues second the velocity of transmission third, the direction of energy and fourth, the density of the tissue." The amount of energy transmitted to the tissues depends mainly upon the velocity of the weapon. Mass times the square of velocity divided by 2 is the formula to calculate the amount of energy. With velocities up to 2,000 feet per second the amount of energy utilized, as evidenced by damage done by the missile, is proportional to the square of the velocity. The time of transmission of energy to the tissues is extremely important and this depends upon the velocity of the injuring object. The shorter the time of transmission, the greater the horse power expended in a unit of time. Callander (30) states that with extremely high velocities the wounding effect of the missile varies as the cube of the velocity and only as a single power of the mass. The density of the tissues is also important. Wilson (218, 219) working with gelatin solutions, concludes that the energy of the missile is dispersed inversely to the square of the percentage density that is in a 5 per cent gelatin solution explosive effects are approximately 4 times as great as in a 10 per cent solution, 9 times as great as in a 15 per cent solution and 16 times as great as in a 20 per cent solution. The velocity imparted to the tissues about the track is important in that bits of tissue, bone fragments, and other organic matter may act as secondary missiles with more extensive injury. If a bone is struck by a high velocity missile near the wound of exit, there may be extensive shattering with skin loss. Ordinarily the elasticity of the skin protects it from extensive tears and lacerations. Whereas a discreet wound of entrance and exit may be seen with a high velocity bullet injury of the thigh, the skinned extremity of the same experimental animal will be shattered to bits by the same missile injury (31).

The palpating effect at a distance from the missile track has been the basis for much experimental work. Sir Victor Horsley (104) attributed this to the 'explosive effect' of the bullet in its passage through the tissue. He thought that the rotational activity of the bullet, rather than the muzzle velocity caused the explosive effect. Recently Black, Burns, and Zuckerman (15, 270)

have shown that when a high velocity pellet with out rotational acceleration enters a gelatin cube it causes a tail splash at the entrance. As the missile traverses the gelatin there is a marked swelling and enlargement of the cube to 4 or more times its previous size. This is caused by the formation of a temporary cavity which almost completely disappears as the pellet passes through and the gelatin cube returns to its former size. Black, Burns and Zuckerman (15 220) emphasized that rotation of the bullet on its long axis in rifle in junes is not the cause of the explosive effect. However they admit that a change in the position of the bullet as it enters the tissues or as it passes through the same because of precession, may alter the dimensions of the track, but the temporary cavitation about the track is due to radial velocity imparted to the walls of the track by the passage of the missile. Butler Puckett Harvey and McMillan (23) have studied the passage of spherical missiles with the use of a microsecond x ray apparatus with which x ray pictures may be taken in one-millionth of a second or less. They have shown that in its passage through the cranial cavity the missile causes a large temporary cavity which expands rapidly and undergoes several pulsations before the tissues return to preinjury dimensions. The passage of the missile causes high radial velocity imparted to the tissues about the track which in turn causes the temporary cavity. Within the cranial cavity this produces an intense increase in intracranial pressure with maceration and pulping of tissue at long distances from the missile track and extensive disorganization of the cranial bones with fragmentation and separation at suture lines. In order to show the role of the intracranial contents in such injuries the following experiments were carried out. A cat, under anesthesia, was struck in the head with a sphere $4/32$ of an inch in diameter with an impact velocity of 3 800 feet per second. There was extensive fracturing of the skull with fragmentation and separation at suture lines. In another cat the skull was cleansed of the soft tissues and brain and a similar injury merely caused a wound of entrance from 6 to 8 times larger than the sphere and a small wound of exit only a little larger than the missile. The comparison of the perforations of the skull in this instance with the extreme fracturing and fragmentation in the experiment in which the intracranial contents were intact is most convincing.

Wounding by shell fragments has been extremely common in World War II. Only 15 per cent or less of the cranial wounds entering the evacuation hospital were from bullets. The great

est majority of the bullet wounds of the head caused death on the field of battle. Shell fragments vary considerably in size shape, and contour. They may travel at extremely high and then again at low velocities. The irregular contour causes extensive laceration and the missile is more prone to carry dirt and foreign matter into the body. The mode of injury is essentially the same as with a high velocity bullet if the fragment is stopped by the body while travelling at a high speed. Severe lacerations of the brain with pulping of the cerebral substance along the track occurs. In many instances penetrating shell fragments remain in the cranial cavity a few may perforate.

In penetrating low velocity wounds such as those caused by knife blade umbrella end or fan blade there may be a tearing of important vascular channels and infection may be introduced into the cranial cavity. The brain about the track of the missile is not pulped and therefore can successfully resist certain amounts and types of infection.

The mechanism of sudden death following penetrating wounds of the brain has been investigated by Polis (156) and Webster and Gurdjian (309). It was observed to be due to a paralysis of the vasomotor and respiratory centers in the medulla. With an increase in the velocity of an injuring bullet, there was a corresponding increase in the severity of the physiological effects.

METHODS OF TREATMENT—WORLD WAR II

Certain generalizations regarding the treatment employed in World War II warrant mention as a preface to the details of operative technique used in high velocity wound management. Among these is the attitude toward patients with cranial wounds. The treatment of this group of patients was undertaken not only from the standpoint of humanitarian obligation for further duty but as a humanitarian obligation. Regardless of the severity of the wound the courage required in the collection of the patient from the point of injury the time employed in primary care, or the efforts consumed in effecting postoperative recovery a conscientious effort was made to accept that responsibility by all personnel involved. This philosophy on the part of surgeons nurses company aid men and hospital corpsmen was a significant factor in the excellence of the care which these patients, in general received.

The campaign in Africa and in Italy early established the value of the neurosurgeon in the Evacuation Hospital and set a pattern which settled any doubt as to where the treatment of

cranial injuries should be carried out, in either a last moving or a stationary type of warfare. Auxiliary surgical teams supplied the personnel for these hospitals if neurosurgeons were not available. Following operation and after a period of observation in the Evacuation Hospital for from 5 to 10 days the neurosurgical patient was evacuated to a "Neurosurgical Center" a general hospital so designated, for late postoperative care and convalescence. General hospitals were deployed as near to major activity as possible, reaching such positions for operation within one month after an invasion.

A second practice of major importance was the modification of neurosurgical operative technique to war wound needs following the suggestion made by Horrax (99) in 1940. The availability of electrocoagulation and efficient suction units resulted in the adoption of more radical measures in débridement. It was also recognized that "brain areas could be wholly or partially removed without detriment to the individual" (99). By the older technique "a careful but necessarily slow and tedious débridement of the wound in the brain was accomplished, an average of two hours being required for the serious, deeply penetrating wounds" (99). By modernizing the technique, operations were performed rapidly with time saving short cuts. Skillful co-operative smooth functioning teamwork usually assisted the surgeon. Ability, experience and confidence acquired in previous training implemented the surgeon's desire to accomplish his purpose as quickly as possible. Laborious attempts at hemostasis were replaced by rapid coagulation. Slow irrigation débridement was replaced with total suction débridement of all devitalized tissue. Modern electrical apparatus provided necessary illumination. From the preparation to the closure of the scalp all but essential manipulations were eliminated.

PRIMARY DÉBRIDEMENT

All cases with scalp wounds were considered as cases of penetrating wounds of the brain unless proved otherwise and all but the obviously fatal wounds were explored (Fig. 2). Following neurological examination, routine roentgen studies of the skull were made. Stereoscopic views were held to be essential by some (31) but the pressure of work or failure of the patient's co-operation often made any additional studies impossible. Visualization of the bone fragments and actual count was attempted. In general, the neurosurgeon was able before operation to visualize the path of the penetrating missile and the degree of bone injury

and imbedding of the bone fragments. Individual surgeons varied in their standards for determining the inoperable patient, but in general, except when the pressure of work was too great, all but the obviously fatal wounds were explored. Particular attention was given to the selection and operation of patients with increased intracerebral bleeding who failed to respond to resuscitation and those with intraventricular wounds (89). Intensive resuscitation measures were employed, consisting mainly of the transfusion of whole blood and plasma, the employment of warmth rest and pain relief and the provision for adequate pulmonary ventilation. Craig (41) has recommended the use of oxygen to help reduce increased intracranial pressure. The high incidence of associated injury (approximately two-thirds of the patients observed by Gaynor and Gurwitz (67)) presented wounds in addition to that of the head) required consideration in planning treatment.

Eden (58) has stated "that there is no doubt that the surgeon who first operates on an open wound makes or mays it—ideally the initial operation should be the final and complete one. The principle of an all or nothing débridement stressed by Cushing (127) was followed in principle although not always attained. The scalp was prepared by complete and thorough shaving and washing about the wound with soap and water for 10 minutes. The use of an antiseptic was elective. Local infiltrative anesthesia was used whenever possible, supplemented by the use of preoperative morphine analgesia. Cairns (14) has objected to the use of morphine, while Horrax (101) believes it may be used in widely open compound wounds. Stemon (178) used local anesthesia in 56 per cent of penetrating brain wounds with a basal narcosis induced by allopoin (gr 35) scopolamine (gr 1/150) and luminal (gr 3). When a general anesthetic was required, the intratracheal administration of ether was preferred. Sodium pentothal has been used with success (129) but caution is required to control the depth of anesthesia (67). Supplementary pentothal anesthesia was used in 25 per cent of the patients operated upon by Munslow (136).

Long curved incisions of the scalp which included the total excision of the wound of entrance were made in place of the 'tripod' type formerly used. They were planned to permit an adequate blood supply to the scalp. The incision was designed with the purpose of securing scalp closure at the end of the operation. The pericranium was carefully removed from the bone defect after débridement since its later use for dural grafting

Fig. 2. Civilian patient presenting a gutter type wound of the right parietal area by a .38-calibre revolver self inflicted. She was operated upon 6 hours after injury. Through curved incisions the area of bone defect was ex-

posed, fragments of bone and pulped brain tissue were removed. The dura was debrided. The dural defect was repaired with a fascia lata graft. The bone defect was subsequently repaired with tantalum.

was possible. The bone defect was enlarged with a rongeur. Frequently a bur opening was necessary, adjacent to the point of entrance. Fragmented bone was removed as well as any additional bone to expose adequately the injured dura and brain. More severe fragmentation of the inner table has often been observed (57). The en bloc method of bone removal was usually not employed. After the excision of damaged dura, the track of the missile in the brain was debrided by suction removal of the devitalized cerebral tissue, blood clot, and bone fragments. A coring of the track to normal tissue was frequently accomplished under direct vision with a lighted retractor as suggested by Horrax (99). The utmost care was employed to spare injury to the cortical vessels. Foreign bodies were extracted if at all possible; the electromagnet being employed by some. Entering the ventricle was avoided but not at the sacrifice of incomplete débridement. Saline solution was used in irrigation of the track and wound although not advised by Munro (8). When doubt existed as to whether all bone fragments were removed, the finger was gently used in the large tracks to feel for the fragments. The dura was closed by means of a graft of pericranium, temporal fascia, fascia lata, or preserved cadaver dura. Cushing silver clips were sometimes used in place of sutures by Havnes (89). In some instances, to conserve time the dura was not closed. Two layer interrupted silk closures were attempted in all cases. Relaxing incisions were not used. In cases of severe scalp loss over a defect of skull and dura, a flap of scalp was used to cover the defect. The bare pericranium was immediately grafted (split thickness). An osteo-

plastic flap has been recommended in the small clean wounds associated with persisting neurological signs for exposing an intracerebral hemorrhage (25). The local instillation of sulfanilamide, penicillin or combinations in the brain track and in the overlying wound was done by some surgeons (26, 58, 171). Cairns (26) stated that in recent brain wounds (up to 72 hours old) penicillin can be applied in a powder (5,000 units of penicillin per gram of sulfanilamide) followed by primary closure of the wound. In 129 cases so treated, fatal infection developed in only 2 cases. He stated also that sulfanilamide and sulfathiazole have been used in some hundreds of brain wounds with no reactions of the kind described by Watt and Alexander (208). Following operation all patients were treated systemically with sulfadiazine or penicillin; the chemotherapy begun at the time of wounding or shortly thereafter being continued. It was discontinued when the wound was healed.

DELAYED PRIMARY DÉBRIDEMENT (24 HOURS—10 DAYS)

The observation first made in World War I that patients with cranial injuries are transportable with greater safety before rather than after operation resulted in a late primary débridement of cranial wounds being done in many instances (7). Unlike patients with delayed wound care in World War I who travelled well but ultimately died of infection, many of these patients survived. Generalized infection was usually prevented by chemotherapy and the localized encephalitis was reduced in degree and even controlled. Thus patients in this class in

Fig. 3. Open exteriorization method of treating brain abscess with graft of fascia lata in patients with massive loss of scalp, skull, and dura. The abscess is totally debrided; a temporary (fascia lata) graft is sutured to the intact dural edge, which prevents leakage of the cerebrospinal fluid and herniation; the scalp is not closed; penicillin solution is injected through the graft into the cavity. The temporary graft is removed in from 15 to 30 days and a split thickness graft applied to the area; the scalp being conserved for cranioplasty.

general, did not present wounds with an extruding brain and meningitis as formerly.
